Scope of this Manual

10/11/2017 • 1 min to read • Edit Online

C is a flexible language that leaves many programming decisions up to you. In keeping with this philosophy, C imposes few restrictions in matters such as type conversion. Although this characteristic of the language can make your programming job easier, you must know the language well to understand how programs will behave. This book provides information on the C language components and the features of the Microsoft implementation. The syntax for the C language is from ANSI X3.159-1989, *American National Standard for Information Systems - Programming Language - C* (hereinafter called the ANSI C standard), although it is not part of the ANSI C standard. C Language Syntax Summary provides the syntax and a description of how to read and use the syntax definitions.

This book does not discuss programming with C++. See C++ Language Reference for information about the C++ language.

ANSI Conformance

10/11/2017 • 1 min to read • Edit Online

Microsoft C conforms to the standard for the C language as set forth in the 9899:1990 edition of the ANSI C standard.

Microsoft extensions to the ANSI C standard are noted in the text and syntax of this book as well as in the online reference. Because the extensions are not a part of the ANSI C standard, their use may restrict portability of programs between systems. By default, the Microsoft extensions are enabled. To disable the extensions, specify the /Za compiler option. With /Za, all non-ANSI code generates errors or warnings.

Elements of C

10/11/2017 • 1 min to read • Edit Online

This section describes the elements of the C programming language, including the names, numbers, and characters used to construct a C program. The ANSI C syntax labels these components tokens.

This section explains how to define tokens and how the compiler evaluates them.

The following topics are discussed:

- Tokens
- Comments
- Keywords
- Identifiers
- Constants
- String literals
- Punctuation and special characters

The section also includes reference tables for Trigraphs, Limits on Floating-Point Constants, C++ Integer Limits, and Escape Sequences.

Operators are symbols (both single characters and character combinations) that specify how values are to be manipulated. Each symbol is interpreted as a single unit, called a token. For more information, see Operators.

C Tokens

10/11/2017 • 1 min to read • Edit Online

In a C source program, the basic element recognized by the compiler is the "token." A token is source-program text that the compiler does not break down into component elements.

Syntax

token:

keyword

identifier

constant

string-literal

operator

punctuator

NOTE

See the introduction to CLanguage Syntax Summary for an explanation of the ANSI syntax conventions.

The keywords, identifiers, constants, string literals, and operators described in this section are examples of tokens. Punctuation characters such as brackets ([]), braces ({}), parentheses (()), and commas (,) are also tokens.

White-Space Characters

10/11/2017 • 1 min to read • Edit Online

Space, tab, linefeed, carriage-return, formfeed, vertical-tab, and newline characters are called "white-space characters" because they serve the same purpose as the spaces between words and lines on a printed page — they make reading easier. Tokens are delimited (bounded) by white-space characters and by other tokens, such as operators and punctuation. When parsing code, the C compiler ignores white-space characters unless you use them as separators or as components of character constants or string literals. Use white-space characters to make a program more readable. Note that the compiler also treats comments as white space.

C Comments

10/11/2017 • 2 min to read • Edit Online

A "comment" is a sequence of characters beginning with a forward slash/asterisk combination (/*) that is treated as a single white-space character by the compiler and is otherwise ignored. A comment can include any combination of characters from the representable character set, including newline characters, but excluding the "end comment" delimiter (*/). Comments can occupy more than one line but cannot be nested.

Comments can appear anywhere a white-space character is allowed. Since the compiler treats a comment as a single white-space character, you cannot include comments within tokens. The compiler ignores the characters in the comment.

Use comments to document your code. This example is a comment accepted by the compiler:

```
/* Comments can contain keywords such as for and while without generating errors. */
```

Comments can appear on the same line as a code statement:

```
printf( "Hello\n" ); /* Comments can go here */
```

You can choose to precede functions or program modules with a descriptive comment block:

```
/* MATHERR.C illustrates writing an error routine
 * for math functions.
 */
```

Since comments cannot contain nested comments, this example causes an error:

```
/* Comment out this routine for testing

/* Open file */
  fh = _open( "myfile.c", _O_RDONLY );
  .
  .
  .
  .
*/
```

The error occurs because the compiler recognizes the first */, after the words Open file, as the end of the comment. It tries to process the remaining text and produces an error when it finds the */ outside a comment.

While you can use comments to render certain lines of code inactive for test purposes, the preprocessor directives <code>#if</code> and <code>#endif</code> and conditional compilation are a useful alternative for this task. For more information, see <code>Preprocessor Directives</code> in the <code>Preprocessor Reference</code>.

Microsoft Specific

The Microsoft compiler also supports single-line comments preceded by two forward slashes (//). If you compile with /Za (ANSI standard), these comments generate errors. These comments cannot extend to a second line.

```
// This is a valid comment
```

Comments beginning with two forward slashes (//) are terminated by the next newline character that is not preceded by an escape character. In the next example, the newline character is preceded by a backslash (\), creating an "escape sequence." This escape sequence causes the compiler to treat the next line as part of the previous line. (For more information, see Escape Sequences.)

```
// my comment \
i++;
```

Therefore, the i++; statement is commented out.

The default for Microsoft C is that the Microsoft extensions are enabled. Use /Za to disable these extensions.

END Microsoft Specific

Evaluation of Tokens

10/11/2017 • 1 min to read • Edit Online

When the compiler interprets tokens, it includes as many characters as possible in a single token before moving on to the next token. Because of this behavior, the compiler may not interpret tokens as you intended if they are not properly separated by white space. Consider the following expression:

i+++j

In this example, the compiler first makes the longest possible operator $(\underbrace{++})$ from the three plus signs, then processes the remaining plus sign as an addition operator $(\underbrace{++})$. Thus, the expression is interpreted as $(\underbrace{i++}) + (\underbrace{j})$, not $(\underbrace{i}) + (\underbrace{++}\underline{j})$. In this and similar cases, use white space and parentheses to avoid ambiguity and ensure proper expression evaluation.

Microsoft Specific

The C compiler treats a CTRL+Z character as an end-of-file indicator. It ignores any text after CTRL+Z.

C Keywords

10/11/2017 • 1 min to read • Edit Online

"Keywords" are words that have special meaning to the C compiler. In translation phases 7 and 8, an identifier cannot have the same spelling and case as a C keyword. (See a description of translation phases in the *Preprocessor Reference*; for information on identifiers, see <u>Identifiers</u>.) The C language uses the following keywords:

| auto | double | int | struct |
|----------|--------|----------|----------|
| break | else | long | switch |
| case | enum | register | typedef |
| char | extern | return | union |
| const | float | short | unsigned |
| continue | for | signed | void |
| default | goto | sizeof | volatile |
| do | if | static | while |

You cannot redefine keywords. However, you can specify text to be substituted for keywords before compilation by using C preprocessor directives.

Microsoft Specific

The ANSI C standard allows identifiers with two leading underscores to be reserved for compiler implementations. Therefore, the Microsoft convention is to precede Microsoft-specific keyword names with double underscores. These words cannot be used as identifier names. For a description of the ANSI rules for naming identifiers, including the use of double underscores, see Identifiers.

The following keywords and special identifiers are recognized by the Microsoft C compiler:

| _asm | dllimport2 | _int8 | naked2 |
|------------|------------|--------|----------|
| based1 | except | _int16 | _stdcall |
| cdecl | fastcall | _int32 | thread2 |
| declspec | _finally | _int64 | _try |
| dllexport2 | _inline | _leave | |

- 1. The **__based** keyword has limited uses for 32-bit and 64-bit target compilations.
- 2. These are special identifiers when used with **__declspec**; their use in other contexts is not restricted.

Microsoft extensions are enabled by default. To ensure that your programs are fully portable, you can disable Microsoft extensions by specifying the /Za option (compile for ANSI compatibility) during compilation. When you do this, Microsoft-specific keywords are disabled.

When Microsoft extensions are enabled, you can use the keywords listed above in your programs. For ANSI compliance, most of these keywords are prefaced by a double underscore. The four exceptions, **dllexport**, **dllimport**, **naked**, and **thread**, are used only with **__declspec** and therefore do not require a leading double underscore. For backward compatibility, single-underscore versions of the rest of the keywords are supported.

C Identifiers

10/11/2017 • 3 min to read • Edit Online

"Identifiers" or "symbols" are the names you supply for variables, types, functions, and labels in your program. Identifier names must differ in spelling and case from any keywords. You cannot use keywords (either C or Microsoft) as identifiers; they are reserved for special use. You create an identifier by specifying it in the declaration of a variable, type, or function. In this example, result is an identifier for an integer variable, and main and printf are identifier names for functions.

```
#include <stdio.h>
int main()
{
   int result;
   if ( result != 0 )
       printf_s( "Bad file handle\n" );
}
```

Once declared, you can use the identifier in later program statements to refer to the associated value.

A special kind of identifier, called a statement label, can be used in goto statements. (Declarations are described in Declarations and Types Statement labels are described in The goto and Labeled Statements.)

Syntax

identifier:

nondigit

identifier nondigit

identifier digit

nondigit : one of

_abcdefghijklmnopqrstuvwxyz

A B C D E F G H I J K L M N O P Q R S T U V W X Y Z

digit : one of

0123456789

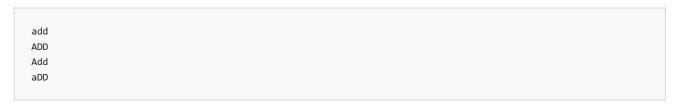

The first character of an identifier name must be a nondigit (that is, the first character must be an underscore or an uppercase or lowercase letter). ANSI allows six significant characters in an external identifier's name and 31 for names of internal (within a function) identifiers. External identifiers (ones declared at global scope or declared with storage class extern) may be subject to additional naming restrictions because these identifiers have to be processed by other software such as linkers.

Microsoft Specific

Although ANSI allows 6 significant characters in external identifier names and 31 for names of internal (within a function) identifiers, the Microsoft C compiler allows 247 characters in an internal or external identifier name. If you aren't concerned with ANSI compatibility, you can modify this default to a smaller or larger number using the /H (restrict length of external names) option.

END Microsoft Specific

The C compiler considers uppercase and lowercase letters to be distinct characters. This feature, called "case sensitivity," enables you to create distinct identifiers that have the same spelling but different cases for one or more of the letters. For example, each of the following identifiers is unique:

Microsoft Specific

Do not select names for identifiers that begin with two underscores or with an underscore followed by an uppercase letter. The ANSI C standard allows identifier names that begin with these character combinations to be reserved for compiler use. Identifiers with file-level scope should also not be named with an underscore and a lowercase letter as the first two letters. Identifier names that begin with these characters are also reserved. By convention, Microsoft uses an underscore and an uppercase letter to begin macro names and double underscores for Microsoft-specific keyword names. To avoid any naming conflicts, always select identifier names that do not begin with one or two underscores, or names that begin with an underscore followed by an uppercase letter.

END Microsoft Specific

The following are examples of valid identifiers that conform to either ANSI or Microsoft naming restrictions:

```
j
count
temp1
top_of_page
skip12
LastNum
```

Microsoft Specific

Although identifiers in source files are case sensitive by default, symbols in object files are not. Microsoft C treats identifiers within a compilation unit as case sensitive.

The Microsoft linker is case sensitive. You must specify all identifiers consistently according to case.

The "source character set" is the set of legal characters that can appear in source files. For Microsoft C, the source set is the standard ASCII character set. The source character set and execution character set include the ASCII characters used as escape sequences. See Character Constants for information about the execution character set.

END Microsoft Specific

An identifier has "scope," which is the region of the program in which it is known, and "linkage," which determines whether the same name in another scope refers to the same identifier. These topics are explained in Lifetime, Scope, Visibility, and Linkage.

Multibyte and Wide Characters

10/11/2017 • 1 min to read • Edit Online

A multibyte character is a character composed of sequences of one or more bytes. Each byte sequence represents a single character in the extended character set. Multibyte characters are used in character sets such as Kanji.

Wide characters are multilingual character codes that are always 16 bits wide. The type for character constants is char; for wide characters, the type is wchar_t. Since wide characters are always a fixed size, using wide characters simplifies programming with international character sets.

The wide-character-string literal L"hello" becomes an array of six integers of type wchar_t .

```
{L'h', L'e', L'l', L'l', L'o', 0}
```

The Unicode specification is the specification for wide characters. The run-time library routines for translating between multibyte and wide characters include mbstowcs, mbtowc, wcstombs, and wctomb.

Trigraphs

10/11/2017 • 1 min to read • Edit Online

The source character set of C source programs is contained within the 7-bit ASCII character set but is a superset of the ISO 646-1983 Invariant Code Set. Trigraph sequences allow C programs to be written using only the ISO (International Standards Organization) Invariant Code Set. Trigraphs are sequences of three characters (introduced by two consecutive question marks) that the compiler replaces with their corresponding punctuation characters. You can use trigraphs in C source files with a character set that does not contain convenient graphic representations for some punctuation characters.

C++17 removes trigraphs from the language. Implementations may continue to support trigraphs as part of the implementation-defined mapping from the physical source file to the *basic source character set*, though the standard encourages implementations not to do so. Through C++14, trigraphs are supported as in C.

Visual C++ continues to support trigraph substitution, but it's disabled by default. For information on how to enable trigraph substitution, see /Zc:trigraphs (Trigraphs Substitution).

The following table shows the nine trigraph sequences. All occurrences in a source file of the punctuation characters in the first column are replaced with the corresponding character in the second column.

Trigraph Sequences

| TRIGRAPH | PUNCTUATION CHARACTER |
|----------|-----------------------|
| ??= | # |
| ??(| [|
| ??/ | \ |
| ??) | 1 |
| ??' | Λ |
| ??< | { |
| ??! | I |
| ??> | } |
| ??- | ~ |

A trigraph is always treated as a single source character. The translation of trigraphs takes place in the first translation phase, before the recognition of escape characters in string literals and character constants. Only the nine trigraphs shown in the above table are recognized. All other character sequences are left untranslated.

The character escape sequence, \?, prevents the misinterpretation of trigraph-like character sequences. (For information about escape sequences, see Escape Sequences.) For example, if you attempt to print the string \[\text{What??!} \] with this \[\text{printf} \] statement

```
printf( "What??!\n" );
```

the string printed is what | because ??! is a trigraph sequence that is replaced with the | character. Write the statement as follows to correctly print the string:

```
printf( "What?\?!\n" );
```

In this printf statement, a backslash escape character in front of the second question mark prevents the misinterpretation of ??! as a trigraph.

C Constants

A "constant" is a number, character, or character string that can be used as a value in a program. Use constants to represent floating-point, integer, enumeration, or character values that cannot be modified.

Syntax

constant:

floating-point-constant

integer-constant

enumeration-constant

character-constant

Constants are characterized by having a value and a type. Floating-point, integer, and character constants are discussed in the next three sections. Enumeration constants are described in Enumeration Declarations.

C Floating-Point Constants

10/11/2017 • 1 min to read • Edit Online

A "floating-point constant" is a decimal number that represents a signed real number. The representation of a signed real number includes an integer portion, a fractional portion, and an exponent. Use floating-point constants to represent floating-point values that cannot be changed.

Syntax

fIFL

```
floating-point-constant:
    fractional-constant exponent-part floating-suffixopt
    digit-sequence exponent-part floating-suffixopt

fractional-constant:
    digit-sequence_opt . digit-sequence
    digit-sequence .

exponent-part:
    e sign_opt digit-sequence
E sign_opt digit-sequence
sign : one of
    + -

digit-sequence digit
floating-suffix : one of
```

You can omit either the digits before the decimal point (the integer portion of the value) or the digits after the decimal point (the fractional portion), but not both. You can leave out the decimal point only if you include an exponent. No white-space characters can separate the digits or characters of the constant.

The following examples illustrate some forms of floating-point constants and expressions:

```
15.75

1.575E1 /* = 15.75 */

1575e-2 /* = 15.75 */

-2.5e-3 /* = -0.0025 */

25E-4 /* = 0.0025 */
```

Floating-point constants are positive unless they are preceded by a minus sign (-). In this case, the minus sign is treated as a unary arithmetic negation operator. Floating-point constants have type float, double, or long double.

A floating-point constant without an **f**, **F**, **I**, or **L** suffix has type double. If the letter **f** or **F** is the suffix, the constant has type float. If suffixed by the letter **I** or **L**, it has type long double. For example:

```
100L /* Has type long double */
100F /* Has type float */
```

Note that the Microsoft C compiler internally represents long double the same as type double. See Storage of Basic Types for information about type double, float, and long double.

You can omit the integer portion of the floating-point constant, as shown in the following examples. The number .75 can be expressed in many ways, including the following:

Integer Types

10/11/2017 • 1 min to read • Edit Online

Every integer constant is given a type based on its value and the way it is expressed. You can force any integer constant to type **long** by appending the letter **l** or **L** to the end of the constant; you can force it to be type unsigned by appending **u** or **U** to the value. The lowercase letter **l** can be confused with the digit 1 and should be avoided. Some forms of **long** integer constants follow:

```
/* Long decimal constants */
10L
79L

/* Long octal constants */
012L
0115L

/* Long hexadecimal constants */
0xaL or 0xAL
0X4FL or 0x4FL

/* Unsigned long decimal constant */
776745UL
778866LU
```

The type you assign to a constant depends on the value the constant represents. A constant's value must be in the range of representable values for its type. A constant's type determines which conversions are performed when the constant is used in an expression or when the minus sign (-) is applied. This list summarizes the conversion rules for integer constants.

- The type for a decimal constant without a suffix is either int, long int, or unsigned long int. The first of these three types in which the constant's value can be represented is the type assigned to the constant.
- The type assigned to octal and hexadecimal constants without suffixes is int , unsigned int , long int, or unsigned long int depending on the size of the constant.
- The type assigned to constants with a **u** or **U** suffix is **unsigned int** or **unsigned long int** depending on their size.
- The type assigned to constants with an I or L suffix is long int or unsigned long int depending on their size.
- The type assigned to constants with a **u** or **U** and an **I** or **L** suffix is **unsigned long int**.

C Character Constants

A "character constant" is formed by enclosing a single character from the representable character set within single quotation marks (' '). Character constants are used to represent characters in the execution character set.

Syntax

character-constant: 'c-char-sequence' L' c-char-sequence ' c-char-sequence: c-char c-char-sequence c-char c-char: Any member of the source character set except the single quotation mark ('), backslash (\), or newline character escape-sequence escape-sequence: simple-escape-sequence octal-escape-sequence hexadecimal-escape-sequence simple-escape-sequence: one of $\a \b \f \n \r \t \v$ \'\"\\\? octal-escape-sequence: **** octal-digit \ octal-digit octal-digit **** octal-digit octal-digit octal-digit hexadecimal-escape-sequence: **\x** hexadecimal-digit

Character Types

10/11/2017 • 1 min to read • Edit Online

An integer character constant not preceded by the letter **L** has type int. The value of an integer character constant containing a single character is the numerical value of the character interpreted as an integer. For example, the numerical value of the character a is 97 in decimal and 61 in hexadecimal.

Syntactically, a "wide-character constant" is a character constant prefixed by the letter **L**. A wide-character constant has type wchar_t, an integer type defined in the STDDEF.H header file. For example:

Wide-character constants are 16 bits wide and specify members of the extended execution character set. They allow you to express characters in alphabets that are too large to be represented by type char. See Multibyte and Wide Characters for more information about wide characters.

Execution Character Set

10/11/2017 • 1 min to read • Edit Online

This content often refers to the "execution character set." The execution character set is not necessarily the same as the source character set used for writing C programs. The execution character set includes all characters in the source character set as well as the null character, newline character, backspace, horizontal tab, vertical tab, carriage return, and escape sequences. The source and execution character sets may differ in other implementations.

Escape Sequences

10/11/2017 • 2 min to read • Edit Online

Character combinations consisting of a backslash (\) followed by a letter or by a combination of digits are called "escape sequences." To represent a newline character, single quotation mark, or certain other characters in a character constant, you must use escape sequences. An escape sequence is regarded as a single character and is therefore valid as a character constant.

Escape sequences are typically used to specify actions such as carriage returns and tab movements on terminals and printers. They are also used to provide literal representations of nonprinting characters and characters that usually have special meanings, such as the double quotation mark ("). The following table lists the ANSI escape sequences and what they represent.

Note that the question mark preceded by a backslash (\?) specifies a literal question mark in cases where the character sequence would be misinterpreted as a trigraph. See Trigraphs for more information.

Escape Sequences

| ESCAPE SEQUENCE | REPRESENTS |
|-----------------|---|
| \a | Bell (alert) |
| \b | Backspace |
| \f | Formfeed |
| \n | New line |
| \r | Carriage return |
| \t | Horizontal tab |
| \v | Vertical tab |
| ν' | Single quotation mark |
| \" | Double quotation mark |
| \\ | Backslash |
| \? | Literal question mark |
| \000 | ASCII character in octal notation |
| \x hh | ASCII character in hexadecimal notation |

| ESCAPE SEQUENCE | REPRESENTS |
|-----------------|--|
| \x hhhh | Unicode character in hexadecimal notation if this escape sequence is used in a wide-character constant or a Unicode string literal. For example, WCHAR f = L'\x4e00' or |
| | <pre>WCHAR b[] = L"The Chinese character for one is \x4e00"</pre> |

Microsoft Specific

If a backslash precedes a character that does not appear in the table, the compiler handles the undefined character as the character itself. For example, \(\cdot \cdot \) is treated as an \(\cdot \cdot \).

END Microsoft Specific

Escape sequences allow you to send nongraphic control characters to a display device. For example, the ESC character (**\033**) is often used as the first character of a control command for a terminal or printer. Some escape sequences are device-specific. For instance, the vertical-tab and formfeed escape sequences (**\v** and **\f**) do not affect screen output, but they do perform appropriate printer operations.

You can also use the backslash (\) as a continuation character. When a newline character (equivalent to pressing the RETURN key) immediately follows the backslash, the compiler ignores the backslash and the newline character and treats the next line as part of the previous line. This is useful primarily for preprocessor definitions longer than a single line. For example:

```
#define assert(exp) \
( (exp) ? (void) 0:_assert( #exp, __FILE__, __LINE__ ) )
```

Octal and Hexadecimal Character Specifications

10/11/2017 • 1 min to read • Edit Online

The sequence \ooo means you can specify any character in the ASCII character set as a three-digit octal character code. The numerical value of the octal integer specifies the value of the desired character or wide character.

Similarly, the sequence \xhhh allows you to specify any ASCII character as a hexadecimal character code. For example, you can give the ASCII backspace character as the normal C escape sequence (\b), or you can code it as \010 (octal) or \x008 (hexadecimal).

You can use only the digits 0 through 7 in an octal escape sequence. Octal escape sequences can never be longer than three digits and are terminated by the first character that is not an octal digit. Although you do not need to use all three digits, you must use at least one. For example, the octal representation is **\10** for the ASCII backspace character and **\101** for the letter A, as given in an ASCII chart.

Similarly, you must use at least one digit for a hexadecimal escape sequence, but you can omit the second and third digits. Therefore you could specify the hexadecimal escape sequence for the backspace character as either \x8, \x08, or \x008.

The value of the octal or hexadecimal escape sequence must be in the range of representable values for type **unsigned char** for a character constant and type wchar_t for a wide-character constant. See Multibyte and Wide Characters for information on wide-character constants.

Unlike octal escape constants, the number of hexadecimal digits in an escape sequence is unlimited. A hexadecimal escape sequence terminates at the first character that is not a hexadecimal digit. Because hexadecimal digits include the letters **a** through **f**, care must be exercised to make sure the escape sequence terminates at the intended digit. To avoid confusion, you can place octal or hexadecimal character definitions in a macro definition:

```
#define Bell '\x07'
```

For hexadecimal values, you can break the string to show the correct value clearly:

```
"\xabc" /* one character */
"\xab" "c" /* two characters */
```

C String Literals

10/11/2017 • 1 min to read • Edit Online

A "string literal" is a sequence of characters from the source character set enclosed in double quotation marks ("
"). String literals are used to represent a sequence of characters which, taken together, form a null-terminated string. You must always prefix wide-string literals with the letter **L**.

Syntax

```
string-literal:
" s-char-sequence opt"

L" s-char-sequence opt"

s-char-sequence:
s-char
s-char
s-char-sequence s-char
s-char:
any member of the source character set except the double quotation mark ("), backslash (\), or newline character escape-sequence
```

The example below is a simple string literal:

```
char *amessage = "This is a string literal.";
```

All escape codes listed in the Escape Sequences table are valid in string literals. To represent a double quotation mark in a string literal, use the escape sequence \". The single quotation mark (') can be represented without an escape sequence. The backslash (\) must be followed with a second backslash (\) when it appears within a string. When a backslash appears at the end of a line, it is always interpreted as a line-continuation character.

Type for String Literals

10/11/2017 • 1 min to read • Edit Online

String literals have type array of char (that is, **char[]**). (Wide-character strings have type array of wchar_t (that is, **wchar_t[]**).) This means that a string is an array with elements of type char. The number of elements in the array is equal to the number of characters in the string plus one for the terminating null character.

Storage of String Literals

10/11/2017 • 1 min to read • Edit Online

The characters of a literal string are stored in order at contiguous memory locations. An escape sequence (such as \\ or \") within a string literal counts as a single character. A null character (represented by the \0 escape sequence) is automatically appended to, and marks the end of, each string literal. (This occurs during translation phase 7.)

Note that the compiler may not store two identical strings at two different addresses. /GF forces the compiler to place a single copy of identical strings into the executable file.

Remarks

Strings have static storage duration. See Storage Classes for information about storage duration.

String Literal Concatenation

10/11/2017 • 1 min to read • Edit Online

To form string literals that take up more than one line, you can concatenate the two strings. To do this, type a backslash, then press the RETURN key. The backslash causes the compiler to ignore the following newline character. For example, the string literal

```
"Long strings can be bro\
ken into two or more pieces."
```

is identical to the string

```
"Long strings can be broken into two or more pieces."
```

String concatenation can be used anywhere you might previously have used a backslash followed by a newline character to enter strings longer than one line.

To force a new line within a string literal, enter the newline escape sequence (\n) at the point in the string where you want the line broken, as follows:

```
"Enter a number between 1 and 100\nOr press Return"
```

Because strings can start in any column of the source code and long strings can be continued in any column of a succeeding line, you can position strings to enhance source-code readability. In either case, their on-screen representation when output is unaffected. For example:

As long as each part of the string is enclosed in double quotation marks, the parts are concatenated and output as a single string. This concatenation occurs according to the sequence of events during compilation specified by translation phases.

```
"This is the first half of the string, this is the second half"
```

A string pointer, initialized as two distinct string literals separated only by white space, is stored as a single string (pointers are discussed in Pointer Declarations). When properly referenced, as in the following example, the result is identical to the previous example:

In translation phase 6, the multibyte-character sequences specified by any sequence of adjacent string literals or adjacent wide-string literals are concatenated into a single multibyte-character sequence. Therefore, do not design programs to allow modification of string literals during execution. The ANSI C standard specifies that the result of modifying a string is undefined.

Maximum String Length

10/11/2017 • 1 min to read • Edit Online

Microsoft Specific

ANSI compatibility requires a compiler to accept up to 509 characters in a string literal after concatenation. The maximum length of a string literal allowed in Microsoft C is approximately 2,048 bytes. However, if the string literal consists of parts enclosed in double quotation marks, the preprocessor concatenates the parts into a single string, and for each line concatenated, it adds an extra byte to the total number of bytes.

For example, suppose a string consists of 40 lines with 50 characters per line (2,000 characters), and one line with 7 characters, and each line is surrounded by double quotation marks. This adds up to 2,007 bytes plus one byte for the terminating null character, for a total of 2,008 bytes. On concatenation, an extra character is added for each of the first 40 lines. This makes a total of 2,048 bytes. Note, however, that if line continuations (\) are used instead of double quotation marks, the preprocessor does not add an extra character for each line.

While an individual quoted string cannot be longer than 2048 bytes, a string literal of roughly 65535 bytes can be constructed by concatenating strings.

Punctuation and Special Characters

10/11/2017 • 1 min to read • Edit Online

The punctuation and special characters in the C character set have various uses, from organizing program text to defining the tasks that the compiler or the compiled program carries out. They do not specify an operation to be performed. Some punctuation symbols are also operators (see Operators). The compiler determines their use from context.

Syntax

punctuator : one of ()[]{}*,:=;...#

These characters have special meanings in C. Their uses are described throughout this book. The pound sign (#) can occur only in preprocessing directives.

Source Files and Source Programs

10/11/2017 • 1 min to read • Edit Online

A source program can be divided into one or more "source files," or "translation units." The input to the compiler is called a "translation unit."

Syntax

translation-unit:
external-declaration

translation-unit external-declaration

external-declaration: function-definition

declaration

Overview of Declarations gives the syntax for the declaration nonterminal, and the *Preprocessor Reference* explains how the translation unit is processed.

NOTE

See the introduction to C Language Syntax Summary, for an explanation of the ANSI syntax conventions.

The components of a translation unit are external declarations that include function definitions and identifier declarations. These declarations and definitions can be in source files, header files, libraries, and other files the program needs. You must compile each translation unit and link the resulting object files to make a program.

A C "source program" is a collection of directives, pragmas, declarations, definitions, statement blocks, and functions. To be valid components of a Microsoft C program, each must have the syntax described in this book, although they can appear in any order in the program (subject to the rules outlined throughout this book). However, the location of these components in a program does affect how variables and functions can be used in a program. (See Lifetime, Scope, Visibility, and Linkage for more information.)

Source files need not contain executable statements. For example, you may find it useful to place definitions of variables in one source file and then declare references to these variables in other source files that use them. This technique makes the definitions easy to find and update when necessary. For the same reason, constants and macros are often organized into separate files called "include files" or "header files" that can be referenced in source files as required. See the *Preprocessor Reference* for information about macros and include files.

Directives to the Preprocessor

10/11/2017 • 1 min to read • Edit Online

A "directive" instructs the C preprocessor to perform a specific action on the text of the program before compilation. Preprocessor directives are fully described in the *Preprocessor Reference*. This example uses the preprocessor directive | #define |:

#define MAX 100

This statement tells the compiler to replace each occurrence of MAX by 100 before compilation. The C compiler preprocessor directives are:

| #DEFINE | #ENDIF | #IFDEF | #LINE |
|---------|--------|----------|---------|
| #elif | #error | #ifndef | #pragma |
| #else | #if | #include | #undef |

C Pragmas

10/11/2017 • 1 min to read • Edit Online

Microsoft Specific

A "pragma" instructs the compiler to perform a particular action at compile time. Pragmas vary from compiler to compiler. For example, you can use the **optimize** pragma to set the optimizations to perform on your program. The Microsoft C pragmas are:

| alloc_text | data_seg | inline_recursion | setlocale |
|-------------|---------------|------------------|-----------|
| auto_inline | function | intrinsic | warning |
| check_stack | hdrstop | message | |
| code_seg | include_alias | optimize | |
| comment | inline_depth | pack | |

See Pragma Directives and the __Pragma Keyword in the *Preprocessor Reference* for a description of the Microsoft C compiler pragmas.

C Declarations and Definitions

10/11/2017 • 1 min to read • Edit Online

A "declaration" establishes an association between a particular variable, function, or type and its attributes.

Overview of Declarations gives the ANSI syntax for the declaration nonterminal. A declaration also specifies where and when an identifier can be accessed (the "linkage" of an identifier). See Lifetime, Scope, Visibility, and Linkage for information about linkage.

A "definition" of a variable establishes the same associations as a declaration but also causes storage to be allocated for the variable.

For example, the main, find, and count functions and the var and val variables are defined in one source file, in this order:

```
int main() {}
int var = 0;
double val[MAXVAL];
char find( fileptr ) {}
int count( double f ) {}
```

The variables var and val can be used in the find and count functions; no further declarations are needed. But these names are not visible (cannot be accessed) in main.

Function Declarations and Definitions

10/11/2017 • 1 min to read • Edit Online

Function prototypes establish the name of the function, its return type, and the type and number of its formal parameters. A function definition includes the function body.

Remarks

Both function and variable declarations can appear inside or outside a function definition. Any declaration within a function definition is said to appear at the "internal" or "local" level. A declaration outside all function definitions is said to appear at the "external," "global," or "file scope" level. Variable definitions, like declarations, can appear at the internal level (within a function definition) or at the external level (outside all function definitions). Function definitions always occur at the external level. Function definitions are discussed further in Function Definitions. Function prototypes are covered in Function Prototypes.

Blocks

10/11/2017 • 1 min to read • Edit Online

A sequence of declarations, definitions, and statements enclosed within curly braces ({ }) is called a "block." There are two types of blocks in C. The "compound statement," a statement composed of one or more statements (see The Compound Statement), is one type of block. The other, the "function definition," consists of a compound statement (the body of the function) plus the function's associated "header" (the function name, return type, and formal parameters). A block within other blocks is said to be "nested."

Note that while all compound statements are enclosed within curly braces, not everything enclosed within curly braces constitutes a compound statement. For example, although the specifications of array, structure, or enumeration elements can appear within curly braces, they are not compound statements.

Example Program

10/11/2017 • 2 min to read • Edit Online

The following C source program consists of two source files. It gives an overview of some of the various declarations and definitions possible in a C program. Later sections in this book describe how to write these declarations, definitions, and initializations, and how to use C keywords such as **static** and extern. The printf function is declared in the C header file STDIO.H.

The main and max functions are assumed to be in separate files, and execution of the program begins with the main function. No explicit user functions are executed before main.

```
FILE1.C - main function
#define ONE 1
#define TWO
#define THREE 3
#include <stdio.h>
             // Defining declarations
// of external variables
int a = 1;
int b = 2;
extern int max( int a, int b ); // Function prototype
int main()
                       // Function definition
                       // for main function
  int c;
int d;
                       // Definitions for
                       // two uninitialized
                       // local variables
  extern int u;
                      // Referencing declaration
                       // of external variable
                       // defined elsewhere
  static int v;
                       // Definition of variable
                       // with continuous lifetime
  int w = ONE, x = TWO, y = THREE;
  int z = 0;
                // Executable statements
  z = max(x, y);
  w = max(z, w);
  printf_s( "%d %d\n", z, w );
  return 0;
}
/***********************
        FILE2.C - definition of max function
int max( int a, int b ) // Note formal parameters are
                      // included in function header
  if(a > b)
     return( a );
    return( b );
}
```

FILE1.C contains the prototype for the max function. This kind of declaration is sometimes called a "forward declaration" because the function is declared before it is used. The definition for the main function includes calls to max.

The lines beginning with #define are preprocessor directives. These directives tell the preprocessor to replace the identifiers ONE, TWO, and THREE with the numbers 1, 2, and 3, respectively, throughout FILE1.C. However, the directives do not apply to FILE2.C, which is compiled separately and then linked with FILE1.C. The line beginning with #include tells the compiler to include the file STDIO.H, which contains the prototype for the printf function. Preprocessor directives are explained in the *Preprocessor Reference*.

FILE1.C uses defining declarations to initialize the global variables a and b. The local variables c and d are declared but not initialized. Storage is allocated for all these variables. The static and external variables, u and v, are automatically initialized to 0. Therefore only a, b, u, and v contain meaningful values when declared because they are initialized, either explicitly or implicitly. FILE2.C contains the function definition for max. This definition satisfies the calls to max in FILE1.C.

The lifetime and visibility of identifiers are discussed in Lifetime, Scope, Visibility, and Linkage. For more information on functions, see Functions.

main Function and Program Execution

10/11/2017 • 1 min to read • Edit Online

Every C program has a primary (main) function that must be named **main**. If your code adheres to the Unicode programming model, you can use the wide-character version of **main**, **wmain**. The **main** function serves as the starting point for program execution. It usually controls program execution by directing the calls to other functions in the program. A program usually stops executing at the end of **main**, although it can terminate at other points in the program for a variety of reasons. At times, perhaps when a certain error is detected, you may want to force the termination of a program. To do so, use the **exit** function. See the *Run-Time Library Reference* for information on and an example using the **exit** function.

Syntax

```
main( int argc, char *argv[ ], char *envp[ ] )
```

Remarks

Functions within the source program perform one or more specific tasks. The **main** function can call these functions to perform their respective tasks. When **main** calls another function, it passes execution control to the function, so that execution begins at the first statement in the function. A function returns control to **main** when a return statement is executed or when the end of the function is reached.

You can declare any function, including **main**, to have parameters. The term "parameter" or "formal parameter" refers to the identifier that receives a value passed to a function. See Parameters for information on passing arguments to parameters. When one function calls another, the called function receives values for its parameters from the calling function. These values are called "arguments." You can declare formal parameters to **main** so that it can receive arguments from the command line using this format:

When you want to pass information to the **main** function, the parameters are traditionally named <code>argc</code> and <code>argv</code>, although the C compiler does not require these names. The types for <code>argc</code> and <code>argv</code> are defined by the C language. Traditionally, if a third parameter is passed to **main**, that parameter is named <code>envp</code>. Examples later in this section show how to use these three parameters to access command-line arguments. The following sections explain these parameters.

See Using wmain for a description of the wide-character version of main.

Using wmain

10/11/2017 • 1 min to read • Edit Online

Microsoft Specific

In the Unicode programming model, you can define a wide-character version of the **main** function. Use **wmain** instead of **main** if you want to write portable code that adheres to the Unicode programming model.

Syntax

```
wmain( int argc, wchar_t *argv[ ], wchar_t *envp[ ] )
```

Remarks

You declare formal parameters to **wmain** using a similar format to **main**. You can then pass wide-character arguments and, optionally, a wide-character environment pointer to the program. The argv and envp parameters to **wmain** are of type wchar_t*. For example:

If your program uses a **main** function, the multibyte-character environment is created by the run-time library at program startup. A wide-character copy of the environment is created only when needed (for example, by a call to the _wgetenv or _wputenv functions). On the first call to _wputenv, or on the first call to _wgetenv if an MBCS environment already exists, a corresponding wide-character string environment is created and is then pointed to by the _wenviron global variable, which is a wide-character version of the _environ global variable. At this point, two copies of the environment (MBCS and Unicode) exist simultaneously and are maintained by the operating system throughout the life of the program.

Similarly, if your program uses a **wmain** function, a wide-character environment is created at program startup and is pointed to by the _wenviron global variable. An MBCS (ASCII) environment is created on the first call to _putenv or _getenv , and is pointed to by the _environ global variable.

For more information on the MBCS environment, see Internationalization in the Run-Time Library Reference.

Argument Description

10/11/2017 • 1 min to read • Edit Online

The argc parameter in the **main** and **wmain** functions is an integer specifying how many arguments are passed to the program from the command line. Since the program name is considered an argument, the value of argc is at least one.

Remarks

The argv parameter is an array of pointers to null-terminated strings representing the program arguments. Each element of the array points to a string representation of an argument passed to **main** (or **wmain**). (For information about arrays, see Array Declarations.) The argv parameter can be declared either as an array of pointers to type char (char *argv[]) or as a pointer to pointers to type char (char *argv[]) or as a pointer to pointers to type wchar_t (wchar_t *argv[]) or as a pointer to pointers to type wchar_t (wchar_t *argv[]).

By convention, argv [0] is the command with which the program is invoked. However, it is possible to spawn a process using CreateProcess and if you use both the first and second arguments (lpApplicationName and lpCommandLine), argv [0] may not be the executable name; use GetModuleFileName to retrieve the executable name.

The last pointer (argv[argc]) is **NULL**. (See getenv in the *Run-Time Library Reference* for an alternative method for getting environment variable information.)

Microsoft Specific

The envp parameter is a pointer to an array of null-terminated strings that represent the values set in the user's environment variables. The envp parameter can be declared as an array of pointers to char (char *envp[]) or as a pointer to pointers to char (char *envp[]) or as a pointer to pointers to wchar_t (wchar_t *envp[]) or as a pointer to pointers to wchar_t (wchar_t *envp[]) or as a pointer to pointers to wchar_t (wchar_t *envp[]). The end of the array is indicated by a **NULL** *pointer. Note that the environment block passed to **main** or **wmain** is a "frozen" copy of the current environment. If you subsequently change the environment via a call to _putenv or _wputenv, the current environment (as returned by getenv / _wgetenv and the _environ or _wenviron variables) will change, but the block pointed to by envp will not change. The envp parameter is ANSI compatible in C, but not in C++.

Expanding Wildcard Arguments

10/11/2017 • 1 min to read • Edit Online

Microsoft Specific

When you run a C program, you can use either of the two wildcards — the question mark (?) and the asterisk (*) — to specify filename and path arguments on the command line.

By default, wildcards are not expanded in command-line arguments. You can replace the normal argument vector argv loading routine with a version that does expand wildcards by linking with the setargv.obj or wsetargv.obj file. If your program uses a main function, link with setargv.obj. If your program uses a wmain function, link with wsetargv.obj. Both of these have equivalent behavior.

To link with setargv.obj or wsetargv.obj, use the /link option. For example:

cl example.c /link setargv.obj

Parsing C Command-Line Arguments

10/11/2017 • 2 min to read • Edit Online

Microsoft Specific

Microsoft C startup code uses the following rules when interpreting arguments given on the operating system command line:

- Arguments are delimited by white space, which is either a space or a tab.
- A string surrounded by double quotation marks is interpreted as a single argument, regardless of white space contained within. A quoted string can be embedded in an argument. Note that the caret (^) is not recognized as an escape character or delimiter.
- A double quotation mark preceded by a backslash, \", is interpreted as a literal double quotation mark (").
- Backslashes are interpreted literally, unless they immediately precede a double quotation mark.
- If an even number of backslashes is followed by a double quotation mark, then one backslash (\) is placed in the argv array for every pair of backslashes (\), and the double quotation mark (") is interpreted as a string delimiter.
- If an odd number of backslashes is followed by a double quotation mark, then one backslash (\) is placed in the argv array for every pair of backslashes (\) and the double quotation mark is interpreted as an escape sequence by the remaining backslash, causing a literal double quotation mark (") to be placed in argv.

This list illustrates the rules above by showing the interpreted result passed to <code>argv</code> for several examples of command-line arguments. The output listed in the second, third, and fourth columns is from the ARGS.C program that follows the list.

| COMMAND-LINE INPUT | ARGV[1] | ARGV[2] | ARGV[3] |
|--------------------|---------|---------|---------|
| "a b c" d e | a b c | d | е |
| "ab\"c" "\\" d | ab"c | \\ | d |
| a\\\b d"e f"g h | a\\\b | de fg | h |
| a\\\"b c d | a\"b | С | d |
| a\\\\"b c" d e | a\\b c | d | е |

Customizing C Command-Line Processing

10/11/2017 • 1 min to read • Edit Online

If your program does not take command-line arguments, you can save a small amount of space by suppressing use of the library routine that performs command-line processing. This routine is called _setargv (or _wsetargv in the wide-character environment), as described in Expanding Wildcard Arguments. To suppress its use, define a routine that does nothing in the file containing the main function and name it _setargv (or _wsetargv in the wide-character environment). The call to _setargv or _wsetargv is then satisfied by your definition of _setargv or _wsetargv , and the library version is not loaded.

Similarly, if you never access the environment table through the envp argument, you can provide your own empty routine to be used in place of _setenvp (or _wsetenvp), the environment-processing routine.

If your program makes calls to the **_spawn** or **_exec** family of routines in the C run-time library, you should not suppress the environment-processing routine, since this routine is used to pass an environment from the spawning process to the new process.

Lifetime, Scope, Visibility, and Linkage

10/11/2017 • 1 min to read • Edit Online

To understand how a C program works, you must understand the rules that determine how variables and functions can be used in the program. Several concepts are crucial to understanding these rules:

- Lifetime
- Scope and visibility
- Linkage

Program Structure

Lifetime

10/11/2017 • 2 min to read • Edit Online

"Lifetime" is the period during execution of a program in which a variable or function exists. The storage duration of the identifier determines its lifetime.

An identifier declared with the *storage-class-specifier* **static** has static storage duration. Identifiers with static storage duration (also called "global") have storage and a defined value for the duration of a program. Storage is reserved and the identifier's stored value is initialized only once, before program startup. An identifier declared with external or internal linkage also has static storage duration (see Linkage).

An identifier declared without the **static** storage-class specifier has automatic storage duration if it is declared inside a function. An identifier with automatic storage duration (a "local identifier") has storage and a defined value only within the block where the identifier is defined or declared. An automatic identifier is allocated new storage each time the program enters that block, and it loses its storage (and its value) when the program exits the block. Identifiers declared in a function with no linkage also have automatic storage duration.

The following rules specify whether an identifier has global (static) or local (automatic) lifetime:

- All functions have static lifetime. Therefore they exist at all times during program execution. Identifiers
 declared at the external level (that is, outside all blocks in the program at the same level of function
 definitions) always have global (static) lifetimes.
- If a local variable has an initializer, the variable is initialized each time it is created (unless it is declared as **static**). Function parameters also have local lifetime. You can specify global lifetime for an identifier within a block by including the **static** storage-class specifier in its declaration. Once declared **static**, the variable retains its value from one entry of the block to the next.

Although an identifier with a global lifetime exists throughout the execution of the source program (for example, an externally declared variable or a local variable declared with the **static** keyword), it may not be visible in all parts of the program. See Scope and Visibility for information about visibility, and see Storage Classes for a discussion of the *storage-class-specifier* nonterminal.

Memory can be allocated as needed (dynamic) if created through the use of special library routines such as malloc. Since dynamic memory allocation uses library routines, it is not considered part of the language. See the malloc function in the *Run-Time Library Reference*.

Scope and Visibility

10/11/2017 • 2 min to read • Edit Online

An identifier's "visibility" determines the portions of the program in which it can be referenced — its "scope." An identifier is visible (i.e., can be used) only in portions of a program encompassed by its "scope," which may be limited (in order of increasing restrictiveness) to the file, function, block, or function prototype in which it appears. The scope of an identifier is the part of the program in which the name can be used. This is sometimes called "lexical scope." There are four kinds of scope: function, file, block, and function prototype.

All identifiers except labels have their scope determined by the level at which the declaration occurs. The following rules for each kind of scope govern the visibility of identifiers within a program:

File scope

The declarator or type specifier for an identifier with file scope appears outside any block or list of parameters and is accessible from any place in the translation unit after its declaration. Identifier names with file scope are often called "global" or "external." The scope of a global identifier begins at the point of its definition or declaration and terminates at the end of the translation unit.

Function scope

A label is the only kind of identifier that has function scope. A label is declared implicitly by its use in a statement. Label names must be unique within a function. (For more information about labels and label names, see The goto and Labeled Statements.)

Block scope

The declarator or type specifier for an identifier with block scope appears inside a block or within the list of formal parameter declarations in a function definition. It is visible only from the point of its declaration or definition to the end of the block containing its declaration or definition. Its scope is limited to that block and to any blocks nested in that block and ends at the curly brace that closes the associated block. Such identifiers are sometimes called "local variables."

Function-prototype scope

The declarator or type specifier for an identifier with function-prototype scope appears within the list of parameter declarations in a function prototype (not part of the function declaration). Its scope terminates at the end of the function declarator.

The appropriate declarations for making variables visible in other source files are described in Storage Classes. However, variables and functions declared at the external level with the **static** storage-class specifier are visible only within the source file in which they are defined. All other functions are globally visible.

Summary of Lifetime and Visibility

10/11/2017 • 1 min to read • Edit Online

The following table is a summary of lifetime and visibility characteristics for most identifiers. The first three columns give the attributes that define lifetime and visibility. An identifier with the attributes given by the first three columns has the lifetime and visibility shown in the fourth and fifth columns. However, the table does not cover all possible cases. Refer to Storage Classes for more information.

Summary of Lifetime and Visibility

| ATTRIBUTES: | ITEM | STORAGE-CLASS SPECIFIER | RESULT: | VISIBILITY |
|-------------|----------------------------------|-------------------------|---------|---|
| File scope | Variable definition | static | Global | Remainder of source file in which it occurs |
| | Variable declaration | extern | Global | Remainder of source file in which it occurs |
| | Function prototype or definition | static | Global | Single source file |
| | Function prototype | extern | Global | Remainder of source file |
| Block scope | Variable declaration | extern | Global | Block |
| | Variable definition | static | Global | Block |
| | Variable definition | auto or register | Local | Block |

Linkage

10/11/2017 • 1 min to read • Edit Online

Identifier names can refer to different identifiers in different scopes. An identifier declared in different scopes or in the same scope more than once can be made to refer to the same identifier or function by a process called "linkage." Linkage determines the portions of the program in which an identifier can be referenced (its "visibility"). There are three kinds of linkage: internal, external, and no linkage.

See Also

Internal Linkage

10/11/2017 • 1 min to read • Edit Online

If the declaration of a file-scope identifier for an object or a function contains the *storage-class-specifier* **static**, the identifier has internal linkage. Otherwise, the identifier has external linkage. See Storage Classes for a discussion of the *storage-class-specifier* nonterminal.

Within one translation unit, each instance of an identifier with internal linkage denotes the same identifier or function. Internally linked identifiers are unique to a translation unit.

See Also

External Linkage

10/11/2017 • 1 min to read • Edit Online

If the first declaration at file-scope level for an identifier does not use the **static** storage-class specifier, the object has external linkage.

If the declaration of an identifier for a function has no *storage-class-specifier*, its linkage is determined exactly as if it were declared with the *storage-class-specifier* extern. If the declaration of an identifier for an object has file scope and no *storage-class-specifier*, its linkage is external.

An identifier's name with external linkage designates the same function or data object as does any other declaration for the same name with external linkage. The two declarations can be in the same translation unit or in different translation units. If the object or function also has global lifetime, the object or function is shared by the entire program.

No Linkage

10/11/2017 • 1 min to read • Edit Online

If a declaration for an identifier within a block does not include the extern storage-class specifier, the identifier has no linkage and is unique to the function.

The following identifiers have no linkage:

- An identifier declared to be anything other than an object or a function
- An identifier declared to be a function parameter
- A block-scope identifier for an object declared without the extern storage-class specifier

If an identifier has no linkage, declaring the same name again (in a declarator or type specifier) in the same scope level generates a symbol redefinition error.

Name Spaces

10/11/2017 • 2 min to read • Edit Online

The compiler sets up "name spaces" to distinguish between the identifiers used for different kinds of items. The names within each name space must be unique to avoid conflict, but an identical name can appear in more than one name space. This means that you can use the same identifier for two or more different items, provided that the items are in different name spaces. The compiler can resolve references based on the syntactic context of the identifier in the program.

NOTE

Do not confuse the limited C notion of a name space with the C++ "namespace" feature. See Namespaces in the C++ Language Reference for more information.

This list describes the name spaces used in C.

Statement labels

Named statement labels are part of statements. Definitions of statement labels are always followed by a colon but are not part of **case** labels. Uses of statement labels always immediately follow the keyword goto. Statement labels do not have to be distinct from other names or from label names in other functions.

Structure, union, and enumeration tags

These tags are part of structure, union, and enumeration type specifiers and, if present, always immediately follow the reserved words <code>struct</code>, <code>union</code>, or <code>enum</code>. The tag names must be distinct from all other structure, enumeration, or union tags with the same visibility.

Members of structures or unions

Member names are allocated in name spaces associated with each structure and union type. That is, the same identifier can be a component name in any number of structures or unions at the same time. Definitions of component names always occur within structure or union type specifiers. Uses of component names always immediately follow the member-selection operators (-> and .). The name of a member must be unique within the structure or union, but it does not have to be distinct from other names in the program, including the names of members of different structures and unions, or the name of the structure itself.

Ordinary identifiers

All other names fall into a name space that includes variables, functions (including formal parameters and local variables), and enumeration constants. Identifier names have nested visibility, so you can redefine them within blocks.

Typedef names

Typedef names cannot be used as identifiers in the same scope.

For example, since structure tags, structure members, and variable names are in three different name spaces, the three items named student in this example do not conflict. The context of each item allows correct interpretation of each occurrence of student in the program. (For information about structures, see Structure Declarations.)

```
struct student {
  char student[20];
  int class;
  int id;
} student;
```

When student appears after the struct keyword, the compiler recognizes it as a structure tag. When student appears after a member-selection operator (-> or .), the name refers to the structure member. In other contexts, student refers to the structure variable. However, overloading the tag name space is not recommended since it obscures meaning.

This section describes the declaration and initialization of variables, functions, and types. The C language includes a standard set of basic data types. You can also add your own data types, called "derived types," by declaring new ones based on types already defined. The following topics are discussed:

- Overview of declarations
- Storage classes
- Type specifiers
- Type qualifiers
- Declarators and variable declarations
- Interpreting more complex declarators
- Initialization
- Storage of basic types
- Incomplete types
- Typedef declarations
- Extended storage-class attributes

Overview of Declarations

10/11/2017 • 4 min to read • Edit Online

A "declaration" specifies the interpretation and attributes of a set of identifiers. A declaration that also causes storage to be reserved for the object or function named by the identifier is called a "definition." C declarations for variables, functions, and types have this syntax:

Syntax

declaration:

declaration-specifiers attribute-segoptinit-declarator-listopt;

/* attribute-seqopt is Microsoft specific */

declaration-specifiers:

storage-class-specifier declaration-specifiersopt

type-specifier declaration-specifiersopt

type-qualifier declaration-specifiersopt

init-declarator-list:

init-declarator

init-declarator-list, init-declarator

init-declarator:

declarator

declarator = initializer

NOTE

This syntax for declaration is not repeated in the following sections. Syntax in the following sections usually begins with the declarator nonterminal.

The declarations in the *init-declarator-list* contain the identifiers being named; *init* is an abbreviation for initializer. The *init-declarator-list* is a comma-separated sequence of declarators, each of which can have additional type information, or an initializer, or both. The declarator contains the identifiers, if any, being declared. The declaration-specifiers nonterminal consists of a sequence of type and storage-class specifiers that indicate the linkage, storage duration, and at least part of the type of the entities that the declarators denote. Therefore, declarations are made up of some combination of storage-class specifiers, type specifiers, type qualifiers, declarators, and initializers.

Declarations can contain one or more of the optional attributes listed in *attribute-seq*; *seq* is an abbreviation for sequence. These Microsoft-specific attributes perform a variety of functions, which are discussed in detail throughout this book.

In the general form of a variable declaration, *type-specifier* gives the data type of the variable. The *type-specifier* can be a compound, as when the type is modified by **const** or volatile. The declarator gives the name of the variable, possibly modified to declare an array or a pointer type. For example,

int const *fp;

declares a variable named fp as a pointer to a nonmodifiable (**const**) int value. You can define more than one variable in a declaration by using multiple declarators, separated by commas.

A declaration must have at least one declarator, or its type specifier must declare a structure tag, union tag, or members of an enumeration. Declarators provide any remaining information about an identifier. A declarator is an identifier that can be modified with brackets ([]), asterisks (\(\nabla\), or parentheses (**()*) to declare an array, pointer, or function type, respectively. When you declare simple variables (such as character, integer, and floating-point items), or structures and unions of simple variables, the declarator is just an identifier. For more information on declarators, see Declarators and Variable Declarations.

All definitions are implicitly declarations, but not all declarations are definitions. For example, variable declarations that begin with the extern storage-class specifier are "referencing," rather than "defining" declarations. If an external variable is to be referred to before it is defined, or if it is defined in another source file from the one where it is used, an extern declaration is necessary. Storage is not allocated by "referencing" declarations, nor can variables be initialized in declarations.

A storage class or a type (or both) is required in variable declarations. Except for __declspec , only one storage-class specifier is allowed in a declaration and not all storage-class specifiers are permitted in every context. The __declspec storage class is allowed with other storage-class specifiers, and it is allowed more than once. The storage-class specifier of a declaration affects how the declared item is stored and initialized, and which parts of a program can reference the item.

The storage-class-specifier terminals defined in C include **auto**, extern, **register**, **static**, and typedef. In addition, Microsoft C includes the storage-class-specifier terminal __declspec . All storage-class-specifier terminals except typedef and __declspec are discussed in Storage Classes. See Typedef Declarations for information about typedef . See Extended Storage-Class Attributes for information about __declspec .

The location of the declaration within the source program and the presence or absence of other declarations of the variable are important factors in determining the lifetime of variables. There can be multiple redeclarations but only one definition. However, a definition can appear in more than one translation unit. For objects with internal linkage, this rule applies separately to each translation unit, because internally linked objects are unique to a translation unit. For objects with external linkage, this rule applies to the entire program. See Lifetime, Scope, Visibility, and Linkage for more information about visibility.

Type specifiers provide some information about the data types of identifiers. The default type specifier is <u>int</u>. For more information, see Type Specifiers. Type specifiers can also define type tags, structure and union component names, and enumeration constants. For more information see Enumeration Declarations, Structure Declarations, and Union Declarations.

There are two *type-qualifier* terminals: **const** and volatile. These qualifiers specify additional properties of types that are relevant only when accessing objects of that type through I-values. For more information on **const** and volatile, see Type Qualifiers. For a definition of I-values, see L-Value and R-Value Expressions.

C Storage Classes

10/11/2017 • 1 min to read • Edit Online

The "storage class" of a variable determines whether the item has a "global" or "local" lifetime. C calls these two lifetimes "static" and "automatic." An item with a global lifetime exists and has a value throughout the execution of the program. All functions have global lifetimes.

Automatic variables, or variables with local lifetimes, are allocated new storage each time execution control passes to the block in which they are defined. When execution returns, the variables no longer have meaningful values.

C provides the following storage-class specifiers:

| Syntax |
|--|
| storage-class-specifier: auto |
| register |
| static |
| extern |
| typedef |
| declspec (extended-decl-modifier-seq) /* Microsoft Specific */ |
| Except fordeclspec , you can use only one <i>storage-class-specifier</i> in the <i>declaration-specifier</i> in a declaration. If no storage-class specification is made, declarations within a block create automatic objects. |
| Items declared with the auto or register specifier have local lifetimes. Items declared with the static or extern specifier have global lifetimes. |
| Since typedef and declspec are semantically different from the other four <i>storage-class-specifier</i> terminals, they are discussed separately. For specific information on typedef, see Typedef Declarations. For specific information on declspec, see Extended Storage-Class Attributes. |

The placement of variable and function declarations within source files also affects storage class and visibility. Declarations outside all function definitions are said to appear at the "external level." Declarations within function definitions appear at the "internal level."

The exact meaning of each storage-class specifier depends on two factors:

- Whether the declaration appears at the external or internal level
- Whether the item being declared is a variable or a function

Storage-Class Specifiers for External-Level Declarations and Storage-Class Specifiers for Internal-Level Declarations describe the *storage-class-specifier* terminals in each kind of declaration and explain the default behavior when the *storage-class-specifier* is omitted from a variable. Storage-Class Specifiers with Function Declarations discusses storage-class specifiers used with functions.

Declarations and Types

Storage-Class Specifiers for External-Level Declarations

10/11/2017 • 4 min to read • Edit Online

External variables are variables at file scope. They are defined outside any function, and they are potentially available to many functions. Functions can only be defined at the external level and, therefore, cannot be nested. By default, all references to external variables and functions of the same name are references to the same object, which means they have "external linkage." (You can use the **static** keyword to override this. See information later in this section for more details on **static**.)

Variable declarations at the external level are either definitions of variables ("defining declarations"), or references to variables defined elsewhere ("referencing declarations").

An external variable declaration that also initializes the variable (implicitly or explicitly) is a defining declaration of the variable. A definition at the external level can take several forms:

• A variable that you declare with the **static** storage-class specifier. You can explicitly initialize the **static** variable with a constant expression, as described in <u>Initialization</u>. If you omit the initializer, the variable is initialized to 0 by default. For example, these two statements are both considered definitions of the variable k.

```
static int k = 16;
static int k;
```

• A variable that you explicitly initialize at the external level. For example, int j = 3; is a definition of the variable j.

In variable declarations at the external level (that is, outside all functions), you can use the **static** or extern storage-class specifier or omit the storage-class specifier entirely. You cannot use the **auto** and **register** storage-class-specifier terminals at the external level.

Once a variable is defined at the external level, it is visible throughout the rest of the translation unit. The variable is not visible prior to its declaration in the same source file. Also, it is not visible in other source files of the program, unless a referencing declaration makes it visible, as described below.

The rules relating to **static** include:

- Variables declared outside all blocks without the static keyword always retain their values throughout the program. To restrict their access to a particular translation unit, you must use the static keyword. This gives them "internal linkage." To make them global to an entire program, omit the explicit storage class or use the keyword extern (see the rules in the next list). This gives them "external linkage." Internal and external linkage are also discussed in Linkage.
- You can define a variable at the external level only once within a program. You can define another variable
 with the same name and the **static** storage-class specifier in a different translation unit. Since each **static**definition is visible only within its own translation unit, no conflict occurs. This provides a useful way to hide
 identifier names that must be shared among functions of a single translation unit, but not visible to other
 translation units.
- The **static** storage-class specifier can apply to functions as well. If you declare a function **static**, its name is invisible outside of the file in which it is declared.

The rules for using extern are:

- The extern storage-class specifier declares a reference to a variable defined elsewhere. You can use an extern declaration to make a definition in another source file visible, or to make a variable visible prior to its definition in the same source file. Once you have declared a reference to the variable at the external level, the variable is visible throughout the remainder of the translation unit in which the declared reference occurs.
- For an extern reference to be valid, the variable it refers to must be defined once, and only once, at the external level. This definition (without the extern storage class) can be in any of the translation units that make up the program.

Example

The example below illustrates external declarations:

```
/***************************
                 SOURCE FILE ONE
#include <stdio.h>
extern int i; // Reference to i, defined below void next( void ); // Function prototype
int main()
   i++;
   printf_s( "%d\n", i ); // i equals 4
   next();
                     // Definition of i
int i = 3;
void next( void )
   printf_s( "%d\n", i ); // i equals 5
   other();
}
SOURCE FILE TWO
#include <stdio.h>
                  // Reference to i in
extern int i;
                     // first source file
void other( void )
   printf_s( "%d\n", i ); // i equals 6
}
```

The two source files in this example contain a total of three external declarations of i. Only one declaration is a "defining declaration." That declaration,

```
int i = 3;
```

defines the global variable i and initializes it with initial value 3. The "referencing" declaration of i at the top of the first source file using extern makes the global variable visible prior to its defining declaration in the file. The

referencing declaration of i in the second source file also makes the variable visible in that source file. If a defining instance for a variable is not provided in the translation unit, the compiler assumes there is an

```
extern int x;
```

referencing declaration and that a defining reference

```
int x = 0;
```

appears in another translation unit of the program.

All three functions, $\frac{1}{main}$, $\frac{1}{mext}$, and $\frac{1}{mext}$, perform the same task: they increase $\frac{1}{mext}$ and print it. The values 4, 5, and 6 are printed.

If the variable i had not been initialized, it would have been set to 0 automatically. In this case, the values 1, 2, and 3 would have been printed. See Initialization for information about variable initialization.

Storage-Class Specifiers for Internal-Level Declarations

10/11/2017 • 1 min to read • Edit Online

You can use any of four *storage-class-specifier* terminals for variable declarations at the internal level. When you omit the *storage-class-specifier* from such a declaration, the default storage class is **auto**. Therefore, the keyword **auto** is rarely seen in a C program.

See Also

C Storage Classes

auto Storage-Class Specifier

10/11/2017 • 1 min to read • Edit Online

The **auto** storage-class specifier declares an automatic variable, a variable with a local lifetime. An **auto** variable is visible only in the block in which it is declared. Declarations of **auto** variables can include initializers, as discussed in **Initialization**. Since variables with **auto** storage class are not initialized automatically, you should either explicitly initialize them when you declare them, or assign them initial values in statements within the block. The values of uninitialized **auto** variables are undefined. (A local variable of **auto** or **register** storage class is initialized each time it comes in scope if an initializer is given.)

An internal **static** variable (a static variable with local or block scope) can be initialized with the address of any external or **static** item, but not with the address of another **auto** item, because the address of an **auto** item is not a constant.

The Microsoft C/C++ compiler does not honor user requests for register variables. However, for portability all other semantics associated with the **register** keyword are honored by the compiler. For example, you cannot apply the unary address-of operator (&) to a register object nor can the **register** keyword be used on arrays.

static Storage-Class Specifier

10/11/2017 • 1 min to read • Edit Online

A variable declared at the internal level with the **static** storage-class specifier has a global lifetime but is visible only within the block in which it is declared. For constant strings, using **static** is useful because it alleviates the overhead of frequent initialization in often-called functions.

Remarks

If you do not explicitly initialize a **static** variable, it is initialized to 0 by default. Inside a function, **static** causes storage to be allocated and serves as a definition. Internal static variables provide private, permanent storage visible to only a single function.

extern Storage-Class Specifier

10/11/2017 • 2 min to read • Edit Online

A variable declared with the extern storage-class specifier is a reference to a variable with the same name defined at the external level in any of the source files of the program. The internal extern declaration is used to make the external-level variable definition visible within the block. Unless otherwise declared at the external level, a variable declared with the extern keyword is visible only in the block in which it is declared.

Example

This example illustrates internal- and external-level declarations:

```
// extern_StorageClassSpecified.c
#include <stdio.h>
void other( void );
int main()
   // Reference to i, defined below:
   extern int i;
   // Initial value is zero; a is visible only within main:
   static int a;
   // b is stored in a register, if possible:
   register int b = 0;
   // Default storage class is auto:
   int c = 0;
    // Values printed are 1, 0, 0, 0:
   printf_s( "%d\n%d\n%d\n", i, a, b, c );
   other();
   return;
}
int i = 1;
void other( void )
   // Address of global i assigned to pointer variable:
   static int *external_i = &i;
   // i is redefined; global i no longer visible:
   int i = 16;
   // This a is visible only within the other function:
   static int a = 2;
   a += 2;
   // Values printed are 16, 4, and 1:
   printf_s( "%d\n%d\n%d\n", i, a, *external_i );
}
```

In this example, the variable i is defined at the external level with initial value 1. An extern declaration in the main function is used to declare a reference to the external-level i. The **static** variable a is initialized to 0 by default, since the initializer is omitted. The call to printf prints the values 1, 0, 0, and 0.

| In the other function, the address of the global variable i is used to initialize the static pointer variable |
|--|
| external_i . This works because the global variable has static lifetime, meaning its address does not change during |
| program execution. Next, the variable i is redefined as a local variable with initial value 16. This redefinition does |
| not affect the value of the external-level [i], which is hidden by the use of its name for the local variable. The value |
| of the global i is now accessible only indirectly within this block, through the pointer external_i . Attempting to |
| assign the address of the auto variable i to a pointer does not work, since it may be different each time the block |
| is entered. The variable a is declared as a static variable and initialized to 2. This a does not conflict with the a |
| in main, since static variables at the internal level are visible only within the block in which they are declared. |

The variable a is increased by 2, giving 4 as the result. If the other function were called again in the same program, the initial value of a would be 4. Internal **static** variables keep their values when the program exits and then reenters the block in which they are declared.

Storage-Class Specifiers with Function Declarations

10/11/2017 • 1 min to read • Edit Online

You can use either the **static** or the extern storage-class specifier in function declarations. Functions always have global lifetimes.

Microsoft Specific

Function declarations at the internal level have the same meaning as function declarations at the external level. This means that a function is visible from its point of declaration throughout the rest of the translation unit even if it is declared at local scope.

END Microsoft Specific

The visibility rules for functions vary slightly from the rules for variables, as follows:

- A function declared to be **static** is visible only within the source file in which it is defined. Functions in the same source file can call the **static** function, but functions in other source files cannot access it directly by name. You can declare another **static** function with the same name in a different source file without conflict.
- Functions declared as extern are visible throughout all source files in the program (unless you later redeclare such a function as **static**). Any function can call an extern function.
- Function declarations that omit the storage-class specifier are extern by default.

Microsoft Specific

Microsoft allows redefinition of an extern identifier as **static**.

C Type Specifiers

10/11/2017 • 2 min to read • Edit Online

Type specifiers in declarations define the type of a variable or function declaration.

Microsoft Specific

Type checking is now ANSI-compliant, which means that type **short** and type int are distinct types. For example, this is a redefinition in the Microsoft C compiler that was accepted by previous versions of the compiler.

that takes no arguments, and to specify a pointer to an unspecified type. You can use the void type to declare functions that return no value or to declare a pointer to an unspecified type. See Arguments for information on

void when it appears alone within the parentheses following a function name.

```
int myfunc();
short myfunc();
```

This next example also generates a warning about indirection to different types:

```
int *pi;
short *ps;

ps = pi; /* Now generates warning */
```

The Microsoft C compiler also generates warnings for differences in sign. For example:

```
signed int *pi;
unsigned int *pu

pi = pu; /* Now generates warning */
```

Type void expressions are evaluated for side effects. You cannot use the (nonexistent) value of an expression that has type void in any way, nor can you convert a void expression (by implicit or explicit conversion) to any type except void. If you do use an expression of any other type in a context where a void expression is required, its value is discarded.

To conform to the ANSI specification, **void**** cannot be used as **int****. Only **void*** can be used as a pointer to an unspecified type.

END Microsoft Specific

You can create additional type specifiers with typedef declarations, as described in Typedef Declarations. See Storage of Basic Types for information on the size of each type.

Data Type Specifiers and Equivalents

10/11/2017 • 1 min to read • Edit Online

This book generally uses the forms of the type specifiers listed in the following table rather than the long forms, and it assumes that the char type is signed by default. Therefore, throughout this book, char is equivalent to **signed** char.

Type Specifiers and Equivalents

| TYPE SPECIFIER | EQUIVALENT(S) |
|--------------------|---------------------|
| signed char1 | char |
| signed int | signed, int |
| signed short int | short, signed short |
| signed long int | long, signed long |
| unsigned char | |
| unsigned int | unsigned |
| unsigned short int | unsigned short |
| unsigned long int | unsigned long |
| float | _ |
| long double2 | _ |

1 When you make the **char** type unsigned by default (by specifying the /J compiler option), you cannot abbreviate **signed char** as **char**.

2 In 32-bit and 64-bit operating systems, the Microsoft C compiler maps long double to type double.

Microsoft Specific

You can specify the /J compiler option to change the default **char** type from signed to unsigned. When this option is in effect, **char** means the same as **unsigned char**, and you must use the **signed** keyword to declare a signed character value. If a **char** value is explicitly declared signed, the /J option does not affect it, and the value is signed extended when widened to an **int** type. The **char** type is zero-extended when widened to **int** type.

END Microsoft Specific

Type Qualifiers

10/11/2017 • 2 min to read • Edit Online

Type qualifiers give one of two properties to an identifier. The **const** type qualifier declares an object to be nonmodifiable. The volatile type qualifier declares an item whose value can legitimately be changed by something beyond the control of the program in which it appears, such as a concurrently executing thread.

The two type qualifiers, **const** and **volatile**, can appear only once in a declaration. Type qualifiers can appear with any type specifier; however, they cannot appear after the first comma in a multiple item declaration. For example, the following declarations are legal:

```
typedef volatile int VI;
const int ci;
```

These declarations are not legal:

```
typedef int *i, volatile *vi;
float f, const cf;
```

Type qualifiers are relevant only when accessing identifiers as I-values in expressions. See L-Value and R-Value Expressions for information about I-values and expressions.

Syntax

type-qualifier:

constvolatile

The following are legal **const** and volatile declarations:

If the specification of an array type includes type qualifiers, the element is qualified, not the array type. If the specification of the function type includes qualifiers, the behavior is undefined. Neither volatile nor **const** affects the range of values or arithmetic properties of the object.

This list describes how to use **const** and volatile.

- The **const** keyword can be used to modify any fundamental or aggregate type, or a pointer to an object of any type, or a typedef. If an item is declared with only the **const** type qualifier, its type is taken to be **const** int. A **const** variable can be initialized or can be placed in a read-only region of storage. The **const** keyword is useful for declaring pointers to **const** since this requires the function not to change the pointer in any way.
- The compiler assumes that, at any point in the program, a volatile variable can be accessed by an unknown process that uses or modifies its value. Therefore, regardless of the optimizations specified on the command line, the code for each assignment to or reference of a volatile variable must be generated even if it appears to have no effect.

If volatile is used alone, int is assumed. The volatile type specifier can be used to provide reliable access to special memory locations. Use volatile with data objects that may be accessed or altered by signal handlers, by concurrently executing programs, or by special hardware such as memory-mapped I/O control registers. You can declare a variable as volatile for its lifetime, or you can cast a single reference to be volatile.

• An item can be both **const** and volatile, in which case the item could not be legitimately modified by its own program, but could be modified by some asynchronous process.

Declarators and Variable Declarations

10/11/2017 • 2 min to read • Edit Online

The rest of this section describes the form and meaning of declarations for variable types summarized in this list. In particular, the remaining sections explain how to declare the following:

| TYPE OF VARIABLE | DESCRIPTION |
|-----------------------|---|
| Simple variables | Single-value variables with integral or floating-point type |
| Arrays | Variables composed of a collection of elements with the same type |
| Pointers | Variables that point to other variables and contain variable locations (in the form of addresses) instead of values |
| Enumeration variables | Simple variables with integral type that hold one value from a set of named integer constants |
| Structures | Variables composed of a collection of values that can have different types |
| Unions | Variables composed of several values of different types that occupy the same storage space |

A declarator is the part of a declaration that specifies the name that is to be introduced into the program. It can include modifiers such as * (pointer-to) and any of the Microsoft calling-convention keywords.

Microsoft Specific

In the declarator

```
__declspec(thread) char *var;

char is the type specifier, __declspec(thread) and * are the modifiers, and var is the identifier's name.
```

END Microsoft Specific

You use declarators to declare arrays of values, pointers to values, and functions returning values of a specified type. Declarators appear in the array and pointer declarations described later in this section.

Syntax

```
declarator:

pointer<sub>opt</sub> direct-declarator

direct-declarator:

identifier
( declarator )

direct-declarator [ constant-expression<sub>opt</sub> ]

direct-declarator ( parameter-type-list )

direct-declarator ( identifier-list<sub>opt</sub> )
```

pointer:

***** type-qualifier-list_{opt}

***** type-qualifier-list_{opt} pointer

type-qualifier-list:

type-qualifier

type-qualifier-list type-qualifier

NOTE

See the syntax for *declaration* in Overview of Declarations or C Language Syntax Summary for the syntax that references a *declarator*.

When a declarator consists of an unmodified identifier, the item being declared has a base type. If an asterisk (\mathcal{V}\) appears to the left of an identifier, the type is modified to a pointer type. If the identifier is followed by brackets ([\] J*), the type is modified to an array type. If the identifier is followed by parentheses, the type is modified to a function type. For more information about interpreting precedence within declarations, see Interpreting More Complex Declarators.

Each declarator declares at least one identifier. A declarator must include a type specifier to be a complete declaration. The type specifier gives the type of the elements of an array type, the type of object addressed by a pointer type, or the return type of a function.

Array and pointer declarations are discussed in more detail later in this section. The following examples illustrate a few simple forms of declarators:

Microsoft Specific

The Microsoft C compiler does not limit the number of declarators that can modify an arithmetic, structure, or union type. The number is limited only by available memory.

Simple Variable Declarations

10/11/2017 • 1 min to read • Edit Online

The declaration of a simple variable, the simplest form of a direct declarator, specifies the variable's name and type. It also specifies the variable's storage class and data type.

Storage classes or types (or both) are required on variable declarations. Untyped variables (such as var;) generate warnings.

Syntax

declarator : pointer opt

direct-declarator

direct-declarator:

identifier

identifier:

nondigit

identifier nondigit

identifier digit

For arithmetic, structure, union, enumerations, and void types, and for types represented by typedef names, simple declarators can be used in a declaration since the type specifier supplies all the typing information. Pointer, array, and function types require more complicated declarators.

You can use a list of identifiers separated by commas (,) to specify several variables in the same declaration. All variables defined in the declaration have the same base type. For example:

The variables x and y can hold any value in the set defined by the int type for a particular implementation. The simple object z is initialized to the value 1 and is not modifiable.

If the declaration of z was for an uninitialized static variable or was at file scope, it would receive an initial value of 0, and that value would be unmodifiable.

```
unsigned long reply, flag; /* Declares two variables

named reply and flag */
```

In this example, both the variables, reply and flag, have unsigned long type and hold unsigned integral values.

C Enumeration Declarations

10/11/2017 • 3 min to read • Edit Online

An enumeration consists of a set of named integer constants. An enumeration type declaration gives the name of the (optional) enumeration tag and defines the set of named integer identifiers (called the "enumeration set," "enumerator constants," "enumerators," or "members"). A variable with enumeration type stores one of the values of the enumeration set defined by that type.

Variables of enum type can be used in indexing expressions and as operands of all arithmetic and relational operators. Enumerations provide an alternative to the #define preprocessor directive with the advantages that the values can be generated for you and obey normal scoping rules.

In ANSI C, the expressions that define the value of an enumerator constant always have <code>int</code> type; thus, the storage associated with an enumeration variable is the storage required for a single <code>int</code> value. An enumeration constant or a value of enumerated type can be used anywhere the C language permits an integer expression.

Syntax

enum-specifier:
enum identifier opt{ enumerator-list }

enum identifier

The optional *identifier* names the enumeration type defined by *enumerator-list*. This identifier is often called the "tag" of the enumeration specified by the list. A type specifier of the form

```
enum
identifier
{
enumerator-list
}
```

declares *identifier* to be the tag of the enumeration specified by the *enumerator-list* nonterminal. The *enumerator-list* defines the "enumerator content." The *enumerator-list* is described in detail below.

If the declaration of a tag is visible, subsequent declarations that use the tag but omit *enumerator-list* specify the previously declared enumerated type. The tag must refer to a defined enumeration type, and that enumeration type must be in current scope. Since the enumeration type is defined elsewhere, the *enumerator-list* does not appear in this declaration. Declarations of types derived from enumerations and typedef declarations for enumeration types can use the enumeration tag before the enumeration type is defined.

Syntax

enumerator-list:
enumerator
enumerator-list, enumerator

enumerator:
enumeration-constant
enumeration-constant = constant-expression

enumeration-constant: identifier

Each enumeration-constant in an enumeration-list names a value of the enumeration set. By default, the first enumeration-constant is associated with the value 0. The next enumeration-constant in the list is associated with the value of (constant-expression + 1), unless you explicitly associate it with another value. The name of an enumeration-constant is equivalent to its value.

You can use *enumeration-constant* = *constant-expression* to override the default sequence of values. Thus, if *enumeration-constant* = *constant-expression* appears in the *enumerator-list*, the *enumeration-constant* is associated with the value given by *constant-expression*. The *constant-expression* must have int type and can be negative.

The following rules apply to the members of an enumeration set:

- An enumeration set can contain duplicate constant values. For example, you could associate the value 0 with two different identifiers, perhaps named null and zero, in the same set.
- The identifiers in the enumeration list must be distinct from other identifiers in the same scope with the same visibility, including ordinary variable names and identifiers in other enumeration lists.
- Enumeration tags obey the normal scoping rules. They must be distinct from other enumeration, structure, and union tags with the same visibility.

Examples

These examples illustrate enumeration declarations:

```
enum DAY
                /* Defines an enumeration type
                                                 */
   saturday,
               /* Names day and declares a
                                                 */
   sunday = 0, /* variable named workday with
                                                 */
                /* that type
   monday,
   tuesday,
   wednesday,
                /* wednesday is associated with 3 */
   thursday,
   friday
} workday;
```

The value 0 is associated with saturday by default. The identifier sunday is explicitly set to 0. The remaining identifiers are given the values 1 through 5 by default.

In this example, a value from the set DAY is assigned to the variable today.

```
enum DAY today = wednesday;
```

Note that the name of the enumeration constant is used to assign the value. Since the DAY enumeration type was previously declared, only the enumeration tag DAY is necessary.

To explicitly assign an integer value to a variable of an enumerated data type, use a type cast:

```
workday = ( enum DAY ) ( day_value - 1 );
```

This cast is recommended in C but is not required.

```
enum BOOLEAN /* Declares an enumeration data type called BOOLEAN */
{
    false,     /* false = 0, true = 1 */
    true
};
enum BOOLEAN end_flag, match_flag; /* Two variables of type BOOLEAN */
```

This declaration can also be specified as

```
enum BOOLEAN { false, true } end_flag, match_flag;\
```

or as

```
enum BOOLEAN { false, true } end_flag;
enum BOOLEAN match_flag;
```

An example that uses these variables might look like this:

Unnamed enumerator data types can also be declared. The name of the data type is omitted, but variables can be declared. The variable response is a variable of the type defined:

```
enum { yes, no } response;
```

Structure Declarations

10/11/2017 • 4 min to read • Edit Online

A "structure declaration" names a type and specifies a sequence of variable values (called "members" or "fields" of the structure) that can have different types. An optional identifier, called a "tag," gives the name of the structure type and can be used in subsequent references to the structure type. A variable of that structure type holds the entire sequence defined by that type. Structures in C are similar to the types known as "records" in other languages.

Syntax

```
struct-or-union-specifier:
struct-or-union identifier opt{ struct-declaration-list }
struct-or-union identifier
struct-or-union:
struct
union
struct-declaration-list:
struct-declaration
struct-declaration-list struct-declaration
The structure content is defined to be
struct-declaration:
specifier-qualifier-list struct-declarator-list;
specifier-qualifier-list:
type-specifier specifier-qualifier-list opt
type-qualifier specifier-qualifier-list opt
struct-declarator-list:
struct-declarator
struct-declarator-list, struct-declarator
struct-declarator:
declarator
```

The declaration of a structure type does not set aside space for a structure. It is only a template for later declarations of structure variables.

A previously defined *identifier* (tag) can be used to refer to a structure type defined elsewhere. In this case, *struct-declaration-list* cannot be repeated as long as the definition is visible. Declarations of pointers to structures and typedefs for structure types can use the structure tag before the structure type is defined. However, the structure definition must be encountered prior to any actual use of the size of the fields. This is an incomplete definition of the type and the type tag. For this definition to be completed, a type definition must appear later in the same scope.

The struct-declaration-list specifies the types and names of the structure members. A struct-declaration-list

argument contains one or more variable or bit-field declarations.

Each variable declared in *struct-declaration-list* is defined as a member of the structure type. Variable declarations within *struct-declaration-list* have the same form as other variable declarations discussed in this section, except that the declarations cannot contain storage-class specifiers or initializers. The structure members can have any variable types except type void, an incomplete type, or a function type.

A member cannot be declared to have the type of the structure in which it appears. However, a member can be declared as a pointer to the structure type in which it appears as long as the structure type has a tag. This allows you to create linked lists of structures.

Structures follow the same scoping as other identifiers. Structure identifiers must be distinct from other structure, union, and enumeration tags with the same visibility.

Each struct-declaration in a struct-declaration-list must be unique within the list. However, identifier names in a struct-declaration-list do not have to be distinct from ordinary variable names or from identifiers in other structure declaration lists.

Nested structures can also be accessed as though they were declared at the file-scope level. For example, given this declaration:

```
struct a
{
   int x;
   struct b
   {
    int y;
   } var2;
}
```

these declarations are both legal:

```
struct a var3;
struct b var4;
```

Examples

These examples illustrate structure declarations:

```
struct employee  /* Defines a structure variable named temp */
{
   char name[20];
   int id;
   long class;
} temp;
```

The employee structure has three members: name, id, and class. The name member is a 20-element array, and id and class are simple members with int and **long** type, respectively. The identifier employee is the structure identifier.

```
struct employee student, faculty, staff;
```

This example defines three structure variables: student, faculty, and staff. Each structure has the same list of three members. The members are declared to have the structure type employee, defined in the previous example.

The complex structure has two members with **float** type, x and y. The structure type has no tag and is therefore unnamed or anonymous.

```
struct sample  /* Defines a structure named x */
{
   char c;
   float *pf;
   struct sample *next;
} x;
```

The first two members of the structure are a char variable and a pointer to a **float** value. The third member, next, is declared as a pointer to the structure type being defined (sample).

Anonymous structures can be useful when the tag named is not needed. This is the case when one declaration defines all structure instances. For example:

```
struct
{
   int x;
   int y;
} mystruct;
```

Embedded structures are often anonymous.

```
struct somestruct
{
    struct /* Anonymous structure */
    {
        int x, y;
    } point;
    int type;
} w;
```

Microsoft Specific

The compiler allows an unsized or zero-sized array as the last member of a structure. This can be useful if the size of a constant array differs when used in various situations. The declaration of such a structure looks like this:

```
struct identifier{ set-of-declarations type array-name[];};
```

Unsized arrays can appear only as the last member of a structure. Structures containing unsized array declarations can be nested within other structures as long as no further members are declared in any enclosing structures. Arrays of such structures are not allowed. The sizeof operator, when applied to a variable of this type or to the type itself, assumes 0 for the size of the array.

Structure declarations can also be specified without a declarator when they are members of another structure or union. The field names are promoted into the enclosing structure. For example, a nameless structure looks like this:

See Structure and Union Members for information about structure references.

C Bit Fields

10/11/2017 • 2 min to read • Edit Online

In addition to declarators for members of a structure or union, a structure declarator can also be a specified number of bits, called a "bit field." Its length is set off from the declarator for the field name by a colon. A bit field is interpreted as an integral type.

Syntax

struct-declarator:

declarator

type-specifier declarator opt: constant-expression

The constant-expression specifies the width of the field in bits. The type-specifier for the declarator must be unsigned int, signed int, or int, and the constant-expression must be a nonnegative integer value. If the value is zero, the declaration has no declarator. Arrays of bit fields, pointers to bit fields, and functions returning bit fields are not allowed. The optional declarator names the bit field. Bit fields can only be declared as part of a structure. The address-of operator (&) cannot be applied to bit-field components.

Unnamed bit fields cannot be referenced, and their contents at run time are unpredictable. They can be used as "dummy" fields, for alignment purposes. An unnamed bit field whose width is specified as 0 guarantees that storage for the member following it in the *struct-declaration-list* begins on an <code>int</code> boundary.

Bit fields must also be long enough to contain the bit pattern. For example, these two statements are not legal:

```
short a:17; /* Illegal! */
int long y:33; /* Illegal! */
```

This example defines a two-dimensional array of structures named screen.

```
struct
{
    unsigned short icon : 8;
    unsigned short color : 4;
    unsigned short underline : 1;
    unsigned short blink : 1;
} screen[25][80];
```

The array contains 2,000 elements. Each element is an individual structure containing four bit-field members: icon, color, underline, and blink. The size of each structure is two bytes.

Bit fields have the same semantics as the integer type. This means a bit field is used in expressions in exactly the same way as a variable of the same base type would be used, regardless of how many bits are in the bit field.

Microsoft Specific

Bit fields defined as <u>int</u> are treated as signed. A Microsoft extension to the ANSI C standard allows <u>char</u> and **long** types (both **signed** and <u>unsigned</u>) for bit fields. Unnamed bit fields with base type **long**, **short**, or <u>char</u> (**signed** or <u>unsigned</u>) force alignment to a boundary appropriate to the base type.

Bit fields are allocated within an integer from least-significant to most-significant bit. In the following code

```
struct mybitfields
{
    unsigned short a : 4;
    unsigned short b : 5;
    unsigned short c : 7;
} test;

int main( void );
{
    test.a = 2;
    test.b = 31;
    test.c = 0;
}
```

the bits would be arranged as follows:

```
00000001 11110010
ccccccb bbbbaaaa
```

Since the 8086 family of processors stores the low byte of integer values before the high byte, the integer $0\times01F2$ above would be stored in physical memory as $0\timesF2$ followed by 0×01 .

Storage and Alignment of Structures

10/11/2017 • 1 min to read • Edit Online

Microsoft Specific

Structure members are stored sequentially in the order in which they are declared: the first member has the lowest memory address and the last member the highest.

Every data object has an *alignment-requirement*. For structures, the requirement is the largest of its members. Every object is allocated an *offset* so that

offset % alignment-requirement == 0

Adjacent bit fields are packed into the same 1-, 2-, or 4-byte allocation unit if the integral types are the same size and if the next bit field fits into the current allocation unit without crossing the boundary imposed by the common alignment requirements of the bit fields.

To conserve space or to conform to existing data structures, you may want to store structures more or less compactly. The $/\mathbb{Z}p[n]$ compiler option and the #pragma pack control how structure data is "packed" into memory. When you use the $/\mathbb{Z}p[n]$ option, where n is 1, 2, 4, 8, or 16, each structure member after the first is stored on byte boundaries that are either the alignment requirement of the field or the packing size (n), whichever is smaller. Expressed as a formula, the byte boundaries are the

```
min( n, sizeof( item ) )
```

where n is the packing size expressed with the /Zp[n] option and item is the structure member. The default packing size is /Zp8.

To use the pack pragma to specify packing other than the packing specified on the command line for a particular structure, give the pack pragma, where the packing size is 1, 2, 4, 8, or 16, before the structure. To reinstate the packing given on the command line, specify the pack pragma with no arguments.

Bit fields default to size **long** for the Microsoft C compiler. Structure members are aligned on the size of the type or the /Zp[n] size, whichever is smaller. The default size is 4.

Union Declarations

10/11/2017 • 2 min to read • Edit Online

A "union declaration" specifies a set of variable values and, optionally, a tag naming the union. The variable values are called "members" of the union and can have different types. Unions are similar to "variant records" in other languages.

Syntax

```
struct-or-union-specifier:
struct-or-union identifier opt{ struct-declaration-list }
struct-or-union identifier
struct-or-union:
struct
union
struct-declaration-list:
struct-declaration
struct-declaration-list struct-declaration
The union content is defined to be
struct-declaration:
specifier-qualifier-list struct-declarator-list;
specifier-qualifier-list:
type-specifier specifier-qualifier-list opt
type-qualifier specifier-qualifier-list opt
struct-declarator-list:
struct-declarator
struct-declarator-list, struct-declarator
```

A variable with **union** type stores one of the values defined by that type. The same rules govern structure and union declarations. Unions can also have bit fields.

Members of unions cannot have an incomplete type, type void, or function type. Therefore members cannot be an instance of the union but can be pointers to the union type being declared.

A union type declaration is a template only. Memory is not reserved until the variable is declared.

NOTE

If a union of two types is declared and one value is stored, but the union is accessed with the other type, the results are unreliable. For example, a union of **float** and <code>int</code> is declared. A **float** value is stored, but the program later accesses the value as an <code>int</code>. In such a situation, the value would depend on the internal storage of **float** values. The integer value would not be reliable.

Examples

The following are examples of unions:

```
union sign  /* A definition and a declaration */
{
   int svar;
   unsigned uvar;
} number;
```

This example defines a union variable with sign type and declares a variable named number that has two members: svar, a signed integer, and uvar, an unsigned integer. This declaration allows the current value of number to be stored as either a signed or an unsigned value. The tag associated with this union type is sign.

The screen array contains 2,000 elements. Each element of the array is an individual union with two members:

window1 and screenval. The window1 member is a structure with two bit-field members, icon and color. The screenval member is an int. At any given time, each union element holds either the int represented by screenval or the structure represented by window1.

Microsoft Specific

Nested unions can be declared anonymously when they are members of another structure or union. This is an example of a nameless union:

Unions are often nested within a structure that includes a field giving the type of data contained in the union at any particular time. This is an example of a declaration for such a union:

```
struct x
{
    int type_tag;
    union
    {
       int x;
       float y;
    }
}
```

See Structure and Union Members for information about referencing unions.

Storage of Unions

10/11/2017 • 1 min to read • Edit Online

The storage associated with a union variable is the storage required for the largest member of the union. When a smaller member is stored, the union variable can contain unused memory space. All members are stored in the same memory space and start at the same address. The stored value is overwritten each time a value is assigned to a different member. For example:

```
union     /* Defines a union named x */
{
    char *a, b;
    float f[20];
} x;
```

The members of the x union are, in order of their declaration, a pointer to a char value, a char value, and an array of **float** values. The storage allocated for x is the storage required for the 20-element array f, since f is the longest member of the union. Because no tag is associated with the union, its type is unnamed or "anonymous."

Array Declarations

10/11/2017 • 2 min to read • Edit Online

An "array declaration" names the array and specifies the type of its elements. It can also define the number of elements in the array. A variable with array type is considered a pointer to the type of the array elements.

Syntax

declaration:

declaration-specifiers init-declarator-list opt;

init-declarator-list:

init-declarator

init-declarator-list , init-declarator

init-declarator:

declarator

declarator = initializer

declarator:

pointer optdirect-declarator

direct-declarator:

direct-declarator [constant-expression opt]

Because constant-expression is optional, the syntax has two forms:

- The first form defines an array variable. The *constant-expression* argument within the brackets specifies the number of elements in the array. The *constant-expression*, if present, must have integral type, and a value larger than zero. Each element has the type given by *type-specifier*, which can be any type except void. An array element cannot be a function type.
- The second form declares a variable that has been defined elsewhere. It omits the constant-expression
 argument in brackets, but not the brackets. You can use this form only if you previously have initialized the
 array, declared it as a parameter, or declared it as a reference to an array explicitly defined elsewhere in the
 program.

In both forms, *direct-declarator* names the variable and can modify the variable's type. The brackets ([]) following *direct-declarator* modify the declarator to an array type.

Type qualifiers can appear in the declaration of an object of array type, but the qualifiers apply to the elements rather than the array itself.

You can declare an array of arrays (a "multidimensional" array) by following the array declarator with a list of bracketed constant expressions in this form:

```
type-specifier
declarator [constant-expression] [constant-expression] ...
```

Each *constant-expression* in brackets defines the number of elements in a given dimension: two-dimensional arrays have two bracketed expressions, three-dimensional arrays have three, and so on. You can omit the first

constant expression if you have initialized the array, declared it as a parameter, or declared it as a reference to an array explicitly defined elsewhere in the program.

You can define arrays of pointers to various types of objects by using complex declarators, as described in Interpreting More Complex Declarators.

Arrays are stored by row. For example, the following array consists of two rows with three columns each:

```
char A[2][3];
```

The three columns of the first row are stored first, followed by the three columns of the second row. This means that the last subscript varies most quickly.

To refer to an individual element of an array, use a subscript expression, as described in Postfix Operators.

Examples

These examples illustrate array declarations:

```
float matrix[10][15];
```

The two-dimensional array named matrix has 150 elements, each having **float** type.

```
struct {
   float x, y;
} complex[100];
```

This is a declaration of an array of structures. This array has 100 elements; each element is a structure containing two members.

```
extern char *name[];
```

This statement declares the type and name of an array of pointers to char. The actual definition of name occurs elsewhere.

Microsoft Specific

The type of integer required to hold the maximum size of an array is the size of **size_t**. Defined in the header file STDDEF.H, **size_t** is an unsigned int with the range 0x00000000 to 0x7CFFFFFF.

Pointer Declarations

10/11/2017 • 3 min to read • Edit Online

A "pointer declaration" names a pointer variable and specifies the type of the object to which the variable points. A variable declared as a pointer holds a memory address.

Syntax

```
declarator:

pointeropt direct-declarator

direct-declarator:

identifier

(declarator)

direct-declarator [constant-expressionopt]

direct-declarator (parameter-type-list)

direct-declarator (identifier-listopt)

pointer:

\* type-qualifier-listopt

\* type-qualifier-listopt

type-qualifier-list:

type-qualifier

type-qualifier

type-qualifier
```

The *type-specifier* gives the type of the object, which can be any basic, structure, or union type. Pointer variables can also point to functions, arrays, and other pointers. (For information on declaring and interpreting more complex pointer types, refer to Interpreting More Complex Declarators.)

By making the *type-specifier* **void**, you can delay specification of the type to which the pointer refers. Such an item is referred to as a "pointer to **void**" and is written as void *. A variable declared as a pointer to void can be used to point to an object of any type. However, to perform most operations on the pointer or on the object to which it points, the type to which it points must be explicitly specified for each operation. (Variables of type **char** * and type **void** * are assignment-compatible without a type cast.) Such conversion can be accomplished with a type cast (see Type-Cast Conversions for more information).

The *type-qualifier* can be either **const** or **volatile**, or both. These specify, respectively, that the pointer cannot be modified by the program itself (**const**), or that the pointer can legitimately be modified by some process beyond the control of the program (**volatile**). (See Type Qualifiers for more information on **const** and **volatile**.)

The *declarator* names the variable and can include a type modifier. For example, if *declarator* represents an array, the type of the pointer is modified to be a pointer to an array.

You can declare a pointer to a structure, union, or enumeration type before you define the structure, union, or enumeration type. You declare the pointer by using the structure or union tag as shown in the examples below. Such declarations are allowed because the compiler does not need to know the size of the structure or union to allocate space for the pointer variable.

Examples

The following examples illustrate pointer declarations.

```
char *message; /* Declares a pointer variable named message */
```

The *message* pointer points to a variable with **char** type.

```
int *pointers[10]; /* Declares an array of pointers */
```

The pointers array has 10 elements; each element is a pointer to a variable with int type.

```
int (*pointer)[10]; /* Declares a pointer to an array of 10 elements */
```

The pointer variable points to an array with 10 elements. Each element in this array has int type.

The pointer x can be modified to point to a different **int** value, but the value to which it points cannot be modified.

```
const int some_object = 5;
int other_object = 37;
int *const y = &fixed_object;
int volatile *const z = &some_object;
int *const volatile w = &some_object;
```

The variable *y* in these declarations is declared as a constant pointer to an **int** value. The value it points to can be modified, but the pointer itself must always point to the same location: the address of *fixed_object*. Similarly, *z* is a constant pointer, but it is also declared to point to an **int** whose value cannot be modified by the program. The additional specifier **volatile** indicates that although the value of the **const int** pointed to by *z* cannot be modified by the program, it could legitimately be modified by a process running concurrently with the program. The declaration of *w* specifies that the program cannot change the value pointed to and that the program cannot modify the pointer.

```
struct list *next, *previous; /* Uses the tag for list */
```

This example declares two pointer variables, *next* and *previous*, that point to the structure type *list*. This declaration can appear before the definition of the *list* structure type (see the next example), as long as the *list* type definition has the same visibility as the declaration.

```
struct list
{
   char *token;
   int count;
   struct list *next;
} line;
```

The variable *line* has the structure type named *list*. The *list* structure type has three members: the first member is a pointer to a **char** value, the second is an **int** value, and the third is a pointer to another *list* structure.

```
struct id
{
   unsigned int id_no;
   struct name *pname;
} record;
```

The variable *record* has the structure type *id*. Note that *pname* is declared as a pointer to another structure type named *name*. This declaration can appear before the *name* type is defined.

Based Pointers (C)

10/11/2017 • 1 min to read • Edit Online

Microsoft Specific

```
__based (C++ Reference)
```

For the Microsoft 32-bit and 64-bit C compilers, a based pointer is a 32-bit or 64-bit offset from a 32-bit or 64-bit pointer base. Based addressing is useful for exercising control over sections where objects are allocated, thereby decreasing the size of the executable file and increasing execution speed. In general, the form for specifying a based pointer is

```
type
__based(
base
)
declarator
```

The "based on pointer" variant of based addressing enables specification of a pointer as a base. The based pointer, then, is an offset into the memory section starting at the beginning of the pointer on which it is based. Pointers based on pointer addresses are the only form of the __based keyword valid in 32-bit and 64-bit compilations. In such compilations, they are 32-bit or 64-bit displacements from a 32-bit or 64-bit base.

One use for pointers based on pointers is for persistent identifiers that contain pointers. A linked list that consists of pointers based on a pointer can be saved to disk, then reloaded to another place in memory, with the pointers remaining valid.

The following example shows a pointer based on a pointer.

```
void *vpBuffer;

struct llist_t
{
    void __based( vpBuffer ) *vpData;
    struct llist_t __based( vpBuffer ) *llNext;
};
```

The pointer vpBuffer is assigned the address of memory allocated at some later point in the program. The linked list is relocated relative to the value of vpBuffer.

C Abstract Declarators

10/11/2017 • 1 min to read • Edit Online

An abstract declarator is a declarator without an identifier, consisting of one or more pointer, array, or function modifiers. The pointer modifier (\) always precedes the identifier in a declarator; array ([]) and function (**()*) modifiers follow the identifier. Knowing this, you can determine where the identifier would appear in an abstract declarator and interpret the declarator accordingly. See Interpreting More Complex Declarators for additional information and examples of complex declarators. Generally typedef can be used to simplify declarators. See Typedef Declarations.

Abstract declarators can be complex. Parentheses in a complex abstract declarator specify a particular interpretation, just as they do for the complex declarators in declarations.

These examples illustrate abstract declarators:

NOTE

The abstract declarator consisting of a set of empty parentheses, (), is not allowed because it is ambiguous. It is impossible to determine whether the implied identifier belongs inside the parentheses (in which case it is an unmodified type) or before the parentheses (in which case it is a function type).

Interpreting More Complex Declarators

10/11/2017 • 4 min to read • Edit Online

You can enclose any declarator in parentheses to specify a particular interpretation of a "complex declarator." A complex declarator is an identifier qualified by more than one array, pointer, or function modifier. You can apply various combinations of array, pointer, and function modifiers to a single identifier. Generally typedef may be used to simplify declarations. See Typedef Declarations.

In interpreting complex declarators, brackets and parentheses (that is, modifiers to the right of the identifier) take precedence over asterisks (that is, modifiers to the left of the identifier). Brackets and parentheses have the same precedence and associate from left to right. After the declarator has been fully interpreted, the type specifier is applied as the last step. By using parentheses you can override the default association order and force a particular interpretation. Never use parentheses, however, around an identifier name by itself. This could be misinterpreted as a parameter list.

A simple way to interpret complex declarators is to read them "from the inside out," using the following four steps:

- 1. Start with the identifier and look directly to the right for brackets or parentheses (if any).
- 2. Interpret these brackets or parentheses, then look to the left for asterisks.
- 3. If you encounter a right parenthesis at any stage, go back and apply rules 1 and 2 to everything within the parentheses.
- 4. Apply the type specifier.

In this example, the steps are numbered in order and can be interpreted as follows:

- 5. The identifier var is declared as
- 6. a pointer to
- 7. a function returning
- 8. a pointer to
- 9. an array of 10 elements, which are
- 10. pointers to
- 11. char values.

Examples

The following examples illustrate other complex declarations and show how parentheses can affect the meaning of a declaration.

```
int *var[5]; /* Array of pointers to int values */
```

The array modifier has higher priority than the pointer modifier, so var is declared to be an array. The pointer modifier applies to the type of the array elements; therefore, the array elements are pointers to int values.

```
int (*var)[5]; /* Pointer to array of int values */
```

In this declaration for var , parentheses give the pointer modifier higher priority than the array modifier, and var is declared to be a pointer to an array of five int values.

```
long *var( long, long ); /* Function returning pointer to long */
```

Function modifiers also have higher priority than pointer modifiers, so this declaration for var declares var to be a function returning a pointer to a **long** value. The function is declared to take two **long** values as arguments.

```
long (*var)( long, long ); /* Pointer to function returning long */
```

This example is similar to the previous one. Parentheses give the pointer modifier higher priority than the function modifier, and var is declared to be a pointer to a function that returns a **long** value. Again, the function takes two **long** arguments.

The elements of an array cannot be functions, but this declaration demonstrates how to declare an array of pointers to functions instead. In this example, var is declared to be an array of five pointers to functions that return structures with two members. The arguments to the functions are declared to be two structures with the same structure type, both. Note that the parentheses surrounding *var[5] are required. Without them, the declaration is an illegal attempt to declare an array of functions, as shown below:

```
/* ILLEGAL */
struct both *var[5](struct both, struct both);
```

The following statement declares an array of pointers.

```
unsigned int *(* const *name[5][10] ) ( void );
```

The name array has 50 elements organized in a multidimensional array. The elements are pointers to a pointer that is a constant. This constant pointer points to a function that has no parameters and returns a pointer to an unsigned type.

This next example is a function returning a pointer to an array of three **double** values.

```
double ( *var( double (*)[3] ) )[3];
```

In this declaration, a function returns a pointer to an array, since functions returning arrays are illegal. Here var is declared to be a function returning a pointer to an array of three **double** values. The function var takes one argument. The argument, like the return value, is a pointer to an array of three **double** values. The argument type is given by a complex *abstract-declarator*. The parentheses around the asterisk in the argument type are required;

without them, the argument type would be an array of three pointers to **double** values. For a discussion and examples of abstract declarators, see Abstract Declarators.

As the above example shows, a pointer can point to another pointer, and an array can contain arrays as elements. Here var is an array of five elements. Each element is a five-element array of pointers to unions with two members.

```
union sign *(*var[5])[5]; /* Array of pointers to arrays

of pointers to unions */
```

This example shows how the placement of parentheses changes the meaning of the declaration. In this example, var is a five-element array of pointers to five-element arrays of pointers to unions. For examples of how to use typedef to avoid complex declarations, see Typedef Declarations.

Initialization

10/11/2017 • 1 min to read • Edit Online

An "initializer" is a value or a sequence of values to be assigned to the variable being declared. You can set a variable to an initial value by applying an initializer to the declarator in the variable declaration. The value or values of the initializer are assigned to the variable.

The following sections describe how to initialize variables of scalar, aggregate, and string types. "Scalar types" include all the arithmetic types, plus pointers. "Aggregate types" include arrays, structures, and unions.

Initializing Scalar Types

10/11/2017 • 3 min to read • Edit Online

When initializing scalar types, the value of the *assignment-expression* is assigned to the variable. The conversion rules for assignment apply. (See Type Conversions for information on conversion rules.)

Syntax

declaration:

declaration-specifiers init-declarator-list opt;

declaration-specifiers:

storage-class-specifier declaration-specifiers opt

type-specifier declaration-specifiers opt

type-qualifier declaration-specifiers opt

init-declarator-list:

init-declarator-list, init-declarator

init-declarator:

declarator

declarator = initializer /* For scalar initialization */

initializer:

assignment-expression

You can initialize variables of any type, provided that you obey the following rules:

- Variables declared at the file-scope level can be initialized. If you do not explicitly initialize a variable at the external level, it is initialized to 0 by default.
- A constant expression can be used to initialize any global variable declared with the **static** *storage-class-specifier*. Variables declared to be **static** are initialized when program execution begins. If you do not explicitly initialize a global **static** variable, it is initialized to 0 by default, and every member that has pointer type is assigned a null pointer.
- Variables declared with the auto or register storage-class specifier are initialized each time execution
 control passes to the block in which they are declared. If you omit an initializer from the declaration of an
 auto or register variable, the initial value of the variable is undefined. For automatic and register values, the
 initializer is not restricted to being a constant; it can be any expression involving previously defined values,
 even function calls.
- The initial values for external variable declarations and for all static variables, whether external or internal, must be constant expressions. (For more information, see Constant Expressions.) Since the address of any externally declared or static variable is constant, it can be used to initialize an internally declared static pointer variable. However, the address of an auto variable cannot be used as a static initializer because it may be different for each execution of the block. You can use either constant or variable values to initialize auto and register variables.
- If the declaration of an identifier has block scope, and the identifier has external linkage, the declaration

cannot have an initialization.

Examples

The following examples illustrate initializations:

```
int x = 10;
```

The integer variable x is initialized to the constant expression 10.

```
register int *px = 0;
```

The pointer px is initialized to 0, producing a "null" pointer.

```
const int c = (3 * 1024);
```

This example uses a constant expression (3 * 1024) to initialize c to a constant value that cannot be modified because of the **const** keyword.

```
int *b = &x;
```

This statement initializes the pointer b with the address of another variable, x.

```
int *const a = &z;
```

The pointer a is initialized with the address of a variable named z. However, since it is specified to be a **const**, the variable a can only be initialized, never modified. It always points to the same location.

```
int GLOBAL ;
int function( void )
{
   int LOCAL ;
   static int *lp = &LOCAL; /* Illegal initialization */
   static int *gp = &GLOBAL; /* Legal initialization */
   register int *rp = &LOCAL; /* Legal initialization */
}
```

The global variable GLOBAL is declared at the external level, so it has global lifetime. The local variable LOCAL has auto storage class and only has an address during the execution of the function in which it is declared. Therefore, attempting to initialize the static pointer variable 1p with the address of LOCAL is not permitted. The static pointer variable gp can be initialized to the address of GLOBAL because that address is always the same. Similarly, *rp can be initialized because rp is a local variable and can have a nonconstant initializer. Each time the block is entered, LOCAL has a new address, which is then assigned to rp.

Initialization

Initializing Aggregate Types

10/11/2017 • 5 min to read • Edit Online

An "aggregate" type is a structure, union, or array type. If an aggregate type contains members of aggregate types, the initialization rules apply recursively.

Syntax

initializer:
{ initializer-list } /* For aggregate initialization */
{ initializer-list , }
initializer-list:
initializer

initializer-list, initializer

The *initializer-list* is a list of initializers separated by commas. Each initializer in the list is either a constant expression or an initializer list. Therefore, initializer lists can be nested. This form is useful for initializing aggregate members of an aggregate type, as shown in the examples in this section. However, if the initializer for an automatic identifier is a single expression, it need not be a constant expression; it merely needs to have appropriate type for assignment to the identifier.

For each initializer list, the values of the constant expressions are assigned, in order, to the corresponding members of the aggregate variable.

If *initializer-list* has fewer values than an aggregate type, the remaining members or elements of the aggregate type are initialized to 0. The initial value of an automatic identifier not explicitly initialized is undefined. If *initializer-list* has more values than an aggregate type, an error results. These rules apply to each embedded initializer list, as well as to the aggregate as a whole.

A structure's initializer is either an expression of the same type, or a list of initializers for its members enclosed in curly braces ({ }). Unnamed bit-field members are not initialized.

When a union is initialized, *initializer-list* must be a single constant expression. The value of the constant expression is assigned to the first member of the union.

If an array has unknown size, the number of initializers determines the size of the array, and its type becomes complete. There is no way to specify repetition of an initializer in C, or to initialize an element in the middle of an array without providing all preceding values as well. If you need this operation in your program, write the routine in assembly language.

Note that the number of initializers can set the size of the array:

```
int x[ ] = { 0, 1, 2 }
```

If you specify the size and give the wrong number of initializers, however, the compiler generates an error.

Microsoft Specific

The maximum size for an array is defined by **size_t**. Defined in the header file STDDEF.H, **size_t** is an unsigned int with the range 0x00000000 to 0x7CFFFFFF.

Examples

This example shows initializers for an array.

```
int P[4][3] =
{
    { 1, 1, 1 },
    { 2, 2, 2 },
    { 3, 3, 3,},
    { 4, 4, 4,},
};
```

This statement declares P as a four-by-three array and initializes the elements of its first row to 1, the elements of its second row to 2, and so on through the fourth row. Note that the initializer list for the third and fourth rows contains commas after the last constant expression. The last initializer list ({4, 4, 4,},) is also followed by a comma. These extra commas are permitted but are not required; only commas that separate constant expressions from one another, and those that separate one initializer list from another, are required.

If an aggregate member has no embedded initializer list, values are simply assigned, in order, to each member of the subaggregate. Therefore, the initialization in the previous example is equivalent to the following:

```
int P[4][3] =
{
   1, 1, 1, 2, 2, 2, 3, 3, 3, 4, 4, 4
};
```

Braces can also appear around individual initializers in the list and would help to clarify the example above.

When you initialize an aggregate variable, you must be careful to use braces and initializer lists properly. The following example illustrates the compiler's interpretation of braces in more detail:

```
typedef struct
{
    int n1, n2, n3;
} triplet;

triplet nlist[2][3] =
{
    {{ 1, 2, 3}, { 4, 5, 6}, { 7, 8, 9}}, /* Row 1 */
    {{ 10,11,12}, { 13,14,15}, { 16,17,18}} /* Row 2 */
};
```

In this example, <code>nlist</code> is declared as a 2-by-3 array of structures, each structure having three members. Row 1 of the initialization assigns values to the first row of <code>nlist</code>, as follows:

- 1. The first left brace on row 1 signals the compiler that initialization of the first aggregate member of nlist (that is, nlist[0]) is beginning.
- 2. The second left brace indicates that initialization of the first aggregate member of <code>nlist[0]</code> (that is, the structure at <code>nlist[0][0]</code>) is beginning.
- 3. The first right brace ends initialization of the structure <code>nlist[0][0]</code>; the next left brace starts initialization of <code>nlist[0][1]</code>.
- 4. The process continues until the end of the line, where the closing right brace ends initialization of nlist[0].

Row 2 assigns values to the second row of nlist in a similar way. Note that the outer sets of braces enclosing the initializers on rows 1 and 2 are required. The following construction, which omits the outer braces, would cause an error:

```
triplet nlist[2][3] = /* THIS CAUSES AN ERROR */
{
      { 1, 2, 3 },{ 4, 5, 6 },{ 7, 8, 9 }, /* Line 1 */
      { 10,11,12 },{ 13,14,15 },{ 16,17,18 } /* Line 2 */
};
```

In this construction, the first left brace on line 1 starts the initialization of <code>nlist[0]</code>, which is an array of three structures. The values 1, 2, and 3 are assigned to the three members of the first structure. When the next right brace is encountered (after the value 3), initialization of <code>nlist[0]</code> is complete, and the two remaining structures in the three-structure array are automatically initialized to 0. Similarly, <code>{ 4,5,6 }</code> initializes the first structure in the second row of <code>nlist</code>. The remaining two structures of <code>nlist[1]</code> are set to 0. When the compiler encounters the next initializer list (<code>{ 7,8,9 }</code>), it tries to initialize <code>nlist[2]</code>. Since <code>nlist</code> has only two rows, this attempt causes an error.

In this next example, the three int members of x are initialized to 1, 2, and 3, respectively.

```
struct list
{
   int i, j, k;
   float m[2][3];
} x = {
      1,
      2,
      3,
      {4.0, 4.0, 4.0}
   };
```

In the list structure above, the three elements in the first row of m are initialized to 4.0; the elements of the remaining row of m are initialized to 0.0 by default.

The union variable y, in this example, is initialized. The first element of the union is an array, so the initializer is an aggregate initializer. The initializer list {'1'} assigns values to the first row of the array. Since only one value appears in the list, the element in the first column is initialized to the character 1, and the remaining two elements in the row are initialized to the value 0 by default. Similarly, the first element of the second row of x is initialized to the character 4, and the remaining two elements in the row are initialized to the value 0.

Initializing Strings

10/11/2017 • 1 min to read • Edit Online

You can initialize an array of characters (or wide characters) with a string literal (or wide string literal). For example:

```
char code[ ] = "abc";
```

initializes code as a four-element array of characters. The fourth element is the null character, which terminates all string literals.

An identifier list can only be as long as the number of identifiers to be initialized. If you specify an array size that is shorter than the string, the extra characters are ignored. For example, the following declaration initializes code as a three-element character array:

```
char code[3] = "abcd";
```

Only the first three characters of the initializer are assigned to code. The character d and the string-terminating null character are discarded. Note that this creates an unterminated string (that is, one without a 0 value to mark its end) and generates a diagnostic message indicating this condition.

The declaration

```
char s[] = "abc", t[3] = "abc";
```

is identical to

```
char s[] = {'a', 'b', 'c', '\0'},
t[3] = {'a', 'b', 'c' };
```

If the string is shorter than the specified array size, the remaining elements of the array are initialized to 0.

Microsoft Specific

In Microsoft C, string literals can be up to 2048 bytes in length.

Storage of Basic Types

10/11/2017 • 1 min to read • Edit Online

The following table summarizes the storage associated with each basic type.

Sizes of Fundamental Types

| ТҮРЕ | STORAGE |
|----------------------------------|---------|
| char, unsigned char, signed char | 1 byte |
| short, unsigned short | 2 bytes |
| int , unsigned int | 4 bytes |
| long, unsigned long | 4 bytes |
| float | 4 bytes |
| double | 8 bytes |
| long double | 8 bytes |

The C data types fall into general categories. The "integral types" include char, int, short, long, signed, unsigned, and enum. The "floating types" include float, double, and long double. The "arithmetic types" include all floating and integral types.

Type char

10/11/2017 • 1 min to read • Edit Online

The char type is used to store the integer value of a member of the representable character set. That integer value is the ASCII code corresponding to the specified character.

Microsoft Specific

Character values of type unsigned char have a range from 0 to 0xFF hexadecimal. A **signed char** has range 0x80 to 0x7F. These ranges translate to 0 to 255 decimal, and -128 to +127 decimal, respectively. The /J compiler option changes the default from **signed** to unsigned.

Type int

10/11/2017 • 1 min to read • Edit Online

The size of a signed or unsigned int item is the standard size of an integer on a particular machine. For example, in 16-bit operating systems, the int type is usually 16 bits, or 2 bytes. In 32-bit operating systems, the int type is usually 32 bits, or 4 bytes. Thus, the int type is equivalent to either the short int or the long int type, and the unsigned int type is equivalent to either the unsigned long type, depending on the target environment. The int types all represent signed values unless specified otherwise.

The type specifiers int and unsigned int (or simply unsigned) define certain features of the C language (for instance, the enum type). In these cases, the definitions of int and unsigned int for a particular implementation determine the actual storage.

Microsoft Specific

Signed integers are represented in two's-complement form. The most-significant bit holds the sign: 1 for negative, 0 for positive and zero. The range of values is given in C++ Integer Limits, which is taken from the LIMITS.H header file

END Microsoft Specific

NOTE

The int and unsigned int type specifiers are widely used in C programs because they allow a particular machine to handle integer values in the most efficient way for that machine. However, since the sizes of the int and unsigned int types vary, programs that depend on a specific int size may not be portable to other machines. To make programs more portable, you can use expressions with the sizeof operator (as discussed in The sizeof Operator) instead of hard-coded data sizes.

C Sized Integer Types

10/11/2017 • 1 min to read • Edit Online

Microsoft Specific

Microsoft C features support for sized integer types. You can declare 8-, 16-, 32-, or 64-bit integer variables by using the __intn type specifier, where n is the size, in bits, of the integer variable. The value of n can be 8, 16, 32, or 64. The following example declares one variable of each of the four types of sized integers:

```
__int8 nSmall; // Declares 8-bit integer
__int16 nMedium; // Declares 16-bit integer
__int32 nLarge; // Declares 32-bit integer
__int64 nHuge; // Declares 64-bit integer
```

The first three types of sized integers are synonyms for the ANSI types that have the same size, and are useful for writing portable code that behaves identically across multiple platforms. Note that the __int8 data type is synonymous with type char, __int16 is synonymous with type short, and __int32 is synonymous with type int. The __int64 type has no equivalent ANSI counterpart.

Type float

10/11/2017 • 3 min to read • Edit Online

Floating-point numbers use the IEEE (Institute of Electrical and Electronics Engineers) format. Single-precision values with float type have 4 bytes, consisting of a sign bit, an 8-bit excess-127 binary exponent, and a 23-bit mantissa. The mantissa represents a number between 1.0 and 2.0. Since the high-order bit of the mantissa is always 1, it is not stored in the number. This representation gives a range of approximately 3.4E-38 to 3.4E+38 for type float.

You can declare variables as float or double, depending on the needs of your application. The principal differences between the two types are the significance they can represent, the storage they require, and their range. The following table shows the relationship between significance and storage requirements.

Floating-Point Types

| ТҮРЕ | SIGNIFICANT DIGITS | NUMBER OF BYTES |
|--------|--------------------|-----------------|
| float | 6 - 7 | 4 |
| double | 15 - 16 | 8 |

Floating-point variables are represented by a mantissa, which contains the value of the number, and an exponent, which contains the order of magnitude of the number.

The following table shows the number of bits allocated to the mantissa and the exponent for each floating-point type. The most significant bit of any float or double is always the sign bit. If it is 1, the number is considered negative; otherwise, it is considered a positive number.

Lengths of Exponents and Mantissas

| ТҮРЕ | EXPONENT LENGTH | MANTISSA LENGTH |
|--------|-----------------|-----------------|
| float | 8 bits | 23 bits |
| double | 11 bits | 52 bits |

Because exponents are stored in an unsigned form, the exponent is biased by half its possible value. For type float, the bias is 127; for type double, it is 1023. You can compute the actual exponent value by subtracting the bias value from the exponent value.

The mantissa is stored as a binary fraction greater than or equal to 1 and less than 2. For types float and double, there is an implied leading 1 in the mantissa in the most-significant bit position, so the mantissas are actually 24 and 53 bits long, respectively, even though the most-significant bit is never stored in memory.

Instead of the storage method just described, the floating-point package can store binary floating-point numbers as denormalized numbers. "Denormalized numbers" are nonzero floating-point numbers with reserved exponent values in which the most-significant bit of the mantissa is 0. By using the denormalized format, the range of a floating-point number can be extended at the cost of precision. You cannot control whether a floating-point number is represented in normalized or denormalized form; the floating-point package determines the representation. The floating-point package never uses a denormalized form unless the exponent becomes less than the minimum that can be represented in a normalized form.

The following table shows the minimum and maximum values you can store in variables of each floating-point type. The values listed in this table apply only to normalized floating-point numbers; denormalized floating-point numbers have a smaller minimum value. Note that numbers retained in 80x87 registers are always represented in 80-bit normalized form; numbers can only be represented in denormalized form when stored in 32-bit or 64-bit floating-point variables (variables of type float and type long).

Range of Floating-Point Types

| ТҮРЕ | MINIMUM VALUE | MAXIMUM VALUE |
|--------|----------------------------|----------------------------|
| float | 1.175494351 E - 38 | 3.402823466 E + 38 |
| double | 2.2250738585072014 E - 308 | 1.7976931348623158 E + 308 |

If precision is less of a concern than storage, consider using type float for floating-point variables. Conversely, if precision is the most important criterion, use type double.

Floating-point variables can be promoted to a type of greater significance (from type float to type double). Promotion often occurs when you perform arithmetic on floating-point variables. This arithmetic is always done in as high a degree of precision as the variable with the highest degree of precision. For example, consider the following type declarations:

```
float f_short;
double f_long;
long double f_longer;

f_short = f_short * f_long;
```

In the preceding example, the variable f_{short} is promoted to type double and multiplied by f_{long} ; then the result is rounded to type float before being assigned to f_{short} .

In the following example (which uses the declarations from the preceding example), the arithmetic is done in float (32-bit) precision on the variables; the result is then promoted to type double:

```
f_longer = f_short * f_short;
```

Double precision values with double type have 8 bytes. The format is similar to the float format except that it has an 11-bit excess-1023 exponent and a 52-bit mantissa, plus the implied high-order 1 bit. This format gives a range of approximately 1.7E-308 to 1.7E+308 for type double.

Microsoft Specific

The double type contains 64 bits: 1 for sign, 11 for the exponent, and 52 for the mantissa. Its range is +/-1.7E308 with at least 15 digits of precision.

Incomplete Types

10/11/2017 • 1 min to read • Edit Online

An incomplete type is a type that describes an identifier but lacks information needed to determine the size of the identifier. An "incomplete type" can be:

- A structure type whose members you have not yet specified.
- A union type whose members you have not yet specified.
- An array type whose dimension you have not yet specified.

The void type is an incomplete type that cannot be completed. To complete an incomplete type, specify the missing information. The following examples show how to create and complete the incomplete types.

• To create an incomplete structure type, declare a structure type without specifying its members. In this example, the ps pointer points to an incomplete structure type called student.

```
struct student *ps;
```

• To complete an incomplete structure type, declare the same structure type later in the same scope with its members specified, as in

```
struct student
{
   int num;
}  /* student structure now completed */
```

• To create an incomplete array type, declare an array type without specifying its repetition count. For example:

```
char a[]; /* a has incomplete type */
```

• To complete an incomplete array type, declare the same name later in the same scope with its repetition count specified, as in

```
char a[25]; /* a now has complete type */
```

Typedef Declarations

10/11/2017 • 3 min to read • Edit Online

A typedef declaration is a declaration with typedef as the storage class. The declarator becomes a new type. You can use typedef declarations to construct shorter or more meaningful names for types already defined by C or for types that you have declared. Typedef names allow you to encapsulate implementation details that may change.

A typedef declaration is interpreted in the same way as a variable or function declaration, but the identifier, instead of assuming the type specified by the declaration, becomes a synonym for the type.

Syntax declaration: declaration-specifiers init-declarator-list opt; declaration-specifiers: storage-class-specifier declaration-specifiers opt type-specifier declaration-specifiers opt type-qualifier declaration-specifiers opt storage-class-specifier: typedef type-specifier: void char short int long float double signed unsigned struct-or-union-specifier enum-specifier typedef-name

typedef-name: identifier

Note that a typedef declaration does not create types. It creates synonyms for existing types, or names for types that could be specified in other ways. When a typedef name is used as a type specifier, it can be combined with certain type specifiers, but not others. Acceptable modifiers include **const** and volatile.

Typedef names share the name space with ordinary identifiers (see Name Spaces for more information). Therefore, a program can have a typedef name and a local-scope identifier by the same name. For example:

```
typedef char FlagType;
int main()
{
   int myproc( int )
{
    int FlagType;
}
```

When declaring a local-scope identifier by the same name as a typedef, or when declaring a member of a structure or union in the same scope or in an inner scope, the type specifier must be specified. This example illustrates this constraint:

```
typedef char FlagType;
const FlagType x;
```

To reuse the FlagType name for an identifier, a structure member, or a union member, the type must be provided:

```
const int FlagType; /* Type specifier required */
```

It is not sufficient to say

```
const FlagType; /* Incomplete specification */
```

because the FlagType is taken to be part of the type, not an identifier that is being redeclared. This declaration is taken to be an illegal declaration like

```
int; /* Illegal declaration */
```

You can declare any type with typedef, including pointer, function, and array types. You can declare a typedef name for a pointer to a structure or union type before you define the structure or union type, as long as the definition has the same visibility as the declaration.

Typedef names can be used to improve code readability. All three of the following declarations of signal specify exactly the same type, the first without making use of any typedef names.

```
typedef void fv( int ), (*pfv)( int ); /* typedef declarations */
void ( *signal( int, void (*) (int)) ) ( int );
fv *signal( int, fv * ); /* Uses typedef type */
pfv signal( int, pfv ); /* Uses typedef type */
```

Examples

The following examples illustrate typedef declarations:

```
typedef int WHOLE; /* Declares WHOLE to be a synonym for int */
```

Note that WHOLE could now be used in a variable declaration such as WHOLE i; or const WHOLE i; However, the declaration long WHOLE i; would be illegal.

```
typedef struct club
{
   char name[30];
   int size, year;
} GROUP;
```

This statement declares GROUP as a structure type with three members. Since a structure tag, club, is also specified, either the typedef name (GROUP) or the structure tag can be used in declarations. You must use the struct keyword with the tag, and you cannot use the struct keyword with the typedef name.

```
typedef GROUP *PG; /* Uses the previous typedef name
to declare a pointer */
```

The type PG is declared as a pointer to the GROUP type, which in turn is defined as a structure type.

```
typedef void DRAWF( int, int );
```

This example provides the type DRAWF for a function returning no value and taking two int arguments. This means, for example, that the declaration

```
DRAWF box;
```

is equivalent to the declaration

```
void box( int, int );
```

C Extended Storage-Class Attributes

10/11/2017 • 1 min to read • Edit Online

Microsoft Specific

More up-to-date information on this topic can be found under __declspec (C++ Reference).

Extended attribute syntax simplifies and standardizes the Microsoft-specific extensions to the C language. The storage-class attributes that use extended attribute syntax include thread, naked, dllimport, and dllexport.

The extended attribute syntax for specifying storage-class information uses the __declspec keyword, which specifies that an instance of a given type is to be stored with a Microsoft-specific storage-class attribute (thread, naked, dllimport, or dllexport). Examples of other storage-class modifiers include the static and extern keywords. However, these keywords are part of the ANSI C standard and as such are not covered by extended attribute syntax.

Syntax

storage-class-specifier:

__declspec (extended-decl-modifier-seq) /* Microsoft Specific */

extended-decl-modifier-seq:

extended-decl-modifier opt

extended-decl-modifier-seq extended-decl-modifier

extended-decl-modifier:

thread

naked

dllimport

dllexport

White space separates the declaration modifiers. Note that *extended-decl-modifier-seq* can be empty; in this case, __declspec has no effect.

The thread, naked, dllimport, and dllexport storage-class attributes are a property only of the declaration of the data or function to which they are applied; they do not redefine the type attributes of the function itself. The thread attribute affects data only. The naked attribute affects functions only. The dllimport and dllexport attributes affect functions and data.

Thread Local Storage

10/11/2017 • 2 min to read • Edit Online

Microsoft Specific

Thread Local Storage (TLS) is the mechanism by which each thread in a given multithreaded process allocates storage for thread-specific data. In standard multithreaded programs, data is shared among all threads of a given process, whereas thread local storage is the mechanism for allocating per-thread data. For a complete discussion of threads, see Processes and Threads in the --- --- Windows SDK.

The Microsoft C language includes the extended storage-class attribute, thread, which is used with the __declspec keyword to declare a thread local variable. For example, the following code declares an integer thread local variable and initializes it with a value:

```
__declspec( thread ) int tls_i = 1;
```

These guidelines must be observed when you are declaring statically bound thread local variables:

- The use of __declspec(thread) may interfere with delay loading of DLL imports.
- You can apply the thread attribute only to data declarations and definitions. It cannot be used on function declarations or definitions. For example, the following code generates a compiler error:

```
#define Thread __declspec( thread )
Thread void func(); /* Error */
```

 You can specify the thread attribute only on data items with static storage duration. This includes global data (both static and extern) and local static data. You cannot declare automatic data with the thread attribute. For example, the following code generates compiler errors:

 You must use the thread attribute for the declaration and the definition of thread local data, regardless of whether the declaration and definition occur in the same file or separate files. For example, the following code generates an error:

```
#define Thread __declspec( thread )
extern int tls_i; /* This generates an error, because the */
int Thread tls_i; /* declaration and the definition differ. */
```

 You cannot use the thread attribute as a type modifier. For example, the following code generates a compiler error:

```
char *ch __declspec( thread ); /* Error */
```

• The address of a thread local variable is not considered constant, and any expression involving such an address is not considered a constant expression. This means that you cannot use the address of a thread local variable as an initializer for a pointer. For example, the compiler flags the following code as an error:

```
#define Thread __declspec( thread )
Thread int tls_i;
int *p = &tls_i;  /* Error */
```

• C permits initialization of a variable with an expression involving a reference to itself, but only for objects of nonstatic extent. For example:

Note that a size of expression that includes the variable being initialized does not constitute a reference to itself and is allowed.

• The use of __declspec(thread) may interfere with delay loading of DLL imports.

For more information about using the thread attribute, see Multithreading Topics.

An "operand" is an entity on which an operator acts. An "expression" is a sequence of operators and operands that performs any combination of these actions:

- Computes a value
- Designates an object or function
- Generates side effects

Operands in C include constants, identifiers, strings, function calls, subscript expressions, member-selection expressions, and complex expressions formed by combining operands with operators or by enclosing operands in parentheses. The syntax for these operands is given in Primary Expressions.

Identifiers in Primary Expressions

10/11/2017 • 1 min to read • Edit Online

Identifiers can have integral, **float**, enum, struct, **union**, array, pointer, or function type. An identifier is a primary expression provided it has been declared as designating an object (in which case it is an I-value) or as a function (in which case it is a function designator). See L-Value and R-Value Expressions for a definition of I-value.

The pointer value represented by an array identifier is not a variable, so an array identifier cannot form the left-hand operand of an assignment operation and therefore is not a modifiable l-value.

An identifier declared as a function represents a pointer whose value is the address of the function. The pointer addresses a function returning a value of a specified type. Thus, function identifiers also cannot be I-values in assignment operations. For more information, see Identifiers.

A constant operand has the value and type of the constant value it represents. A character constant has <code>int</code> type. String Literals in Primary Expressions

10/11/2017 • 1 min to read • Edit Online

A "string literal" is a character, wide character, or sequence of adjacent characters enclosed in double quotation marks. Since they are not variables, neither string literals nor any of their elements can be the left-hand operand in an assignment operation. The type of a string literal is an array of char (or an array of wchar_t for wide-string literals). Arrays in expressions are converted to pointers. See String Literals for more information about strings.

Expressions in Parentheses

10/11/2017 • 1 min to read • Edit Online

You can enclose any operand in parentheses without changing the type or value of the enclosed expression. For example, in the expression:

```
( 10 + 5 ) / 5
```

the parentheses around 10 + 5 mean that the value of 10 + 5 is evaluated first and it becomes the left operand of the division (f) operator. The result of (10 + 5) / 5 is 3. Without the parentheses, 10 + 5 / 5 would evaluate to 11.

Although parentheses affect the way operands are grouped in an expression, they cannot guarantee a particular order of evaluation in all cases. For example, neither the parentheses nor the left-to-right grouping of the following expression guarantees what the value of i will be in either of the subexpressions:

```
( i++ +1 ) * ( 2 + i )
```

The compiler is free to evaluate the two sides of the multiplication in any order. If the initial value of i is zero, the whole expression could be evaluated as either of these two statements:

```
( 0 + 1 + 1 ) * ( 2 + 1 )
( 0 + 1 + 1 ) * ( 2 + 0 )
```

Exceptions resulting from side effects are discussed in Side Effects.

L-Value and R-Value Expressions

10/11/2017 • 1 min to read • Edit Online

Expressions that refer to memory locations are called "I-value" expressions. An I-value represents a storage region's "locator" value, or a "left" value, implying that it can appear on the left of the equal sign (=). L-values are often identifiers.

Expressions referring to modifiable locations are called "modifiable l-values." A modifiable l-value cannot have an array type, an incomplete type, or a type with the **const** attribute. For structures and unions to be modifiable l-values, they must not have any members with the **const** attribute. The name of the identifier denotes a storage location, while the value of the variable is the value stored at that location.

An identifier is a modifiable l-value if it refers to a memory location and if its type is arithmetic, structure, union, or pointer. For example, if ptr is a pointer to a storage region, then *ptr is a modifiable l-value that designates the storage region to which ptr points.

Any of the following C expressions can be I-value expressions:

- An identifier of integral, floating, pointer, structure, or union type
- A subscript ([]) expression that does not evaluate to an array
- A member-selection expression (-> or .)
- A unary-indirection (\tau^*) expression that does not refer to an array
- An I-value expression in parentheses
- A const object (a nonmodifiable I-value)

The term "r-value" is sometimes used to describe the value of an expression and to distinguish it from an I-value. All I-values are r-values but not all r-values are I-values.

Microsoft Specific

Microsoft C includes an extension to the ANSI C standard that allows casts of I-values to be used as I-values, as long as the size of the object is not lengthened through the cast. (See Type-Cast Conversions for more information.) The following example illustrates this feature:

The default for Microsoft C is that the Microsoft extensions are enabled. Use the /Za compiler option to disable these extensions.

The nonterminals for struct declarator, enumerator, direct declarator, direct-abstract declarator, and labeled statement contain the *constant-expression* nonterminal.

An integral constant expression must be used to specify the size of a bit-field member of a structure, the value of an enumeration constant, the size of an array, or the value of a **case** constant.

Constant expressions used in preprocessor directives are subject to additional restrictions. Consequently, they are known as "restricted constant expressions." A restricted constant expression cannot contain sizeof expressions, enumeration constants, type casts to any type, or floating-type constants. It can, however, contain the special constant expression defined (identifier).

Expression Evaluation (C)

10/11/2017 • 1 min to read • Edit Online

Expressions involving assignment, unary increment, unary decrement, or calling a function may have consequences incidental to their evaluation (side effects). When a "sequence point" is reached, everything preceding the sequence point, including any side effects, is guaranteed to have been evaluated before evaluation begins on anything following the sequence point.

"Side effects" are changes caused by the evaluation of an expression. Side effects occur whenever the value of a variable is changed by an expression evaluation. All assignment operations have side effects. Function calls can also have side effects if they change the value of an externally visible item, either by direct assignment or by indirect assignment through a pointer.

Side Effects

10/11/2017 • 1 min to read • Edit Online

The order of evaluation of expressions is defined by the specific implementation, except when the language guarantees a particular order of evaluation (as outlined in Precedence and Order of Evaluation). For example, side effects occur in the following function calls:

```
add( i + 1, i = j + 2 );
myproc( getc(), getc() );
```

The arguments of a function call can be evaluated in any order. The expression i + 1 may be evaluated before i = j + 2, or i = j + 2 may be evaluated before i + 1. The result is different in each case. Likewise, it is not possible to guarantee what characters are actually passed to the myproc. Since unary increment and decrement operations involve assignments, such operations can cause side effects, as shown in the following example:

```
x[i] = i++;
```

In this example, the value of x that is modified is unpredictable. The value of the subscript could be either the new or the old value of x. The result can vary under different compilers or different optimization levels.

Since C does not define the order of evaluation of side effects, both evaluation methods discussed above are correct and either may be implemented. To make sure that your code is portable and clear, avoid statements that depend on a particular order of evaluation for side effects.

C Sequence Points

10/11/2017 • 1 min to read • Edit Online

Between consecutive "sequence points" an object's value can be modified only once by an expression. The C language defines the following sequence points:

- Left operand of the logical-AND operator (&&). The left operand of the logical-AND operator is completely
 evaluated and all side effects complete before continuing. If the left operand evaluates to false (0), the other
 operand is not evaluated.
- Left operand of the logical-OR operator (| | |). The left operand of the logical-OR operator is completely evaluated and all side effects complete before continuing. If the left operand evaluates to true (nonzero), the other operand is not evaluated.
- Left operand of the comma operator. The left operand of the comma operator is completely evaluated and all side effects complete before continuing. Both operands of the comma operator are always evaluated. Note that the comma operator in a function call does not guarantee an order of evaluation.
- Function-call operator. All arguments to a function are evaluated and all side effects complete before entry to the function. No order of evaluation among the arguments is specified.
- First operand of the conditional operator. The first operand of the conditional operator is completely evaluated and all side effects complete before continuing.
- The end of a full initialization expression (that is, an expression that is not part of another expression such as the end of an initialization in a declaration statement).
- The expression in an expression statement. Expression statements consist of an optional expression followed by a semicolon (;). The expression is evaluated for its side effects and there is a sequence point following this evaluation.
- The controlling expression in a selection (**if** or switch) statement. The expression is completely evaluated and all side effects complete before the code dependent on the selection is executed.
- The controlling expression of a while or **do** statement. The expression is completely evaluated and all side effects complete before any statements in the next iteration of the while or **do** loop are executed.
- Each of the three expressions of a **for** statement. The expressions are completely evaluated and all side effects complete before any statements in the next iteration of the **for** loop are executed.
- The expression in a return statement. The expression is completely evaluated and all side effects complete before control returns to the calling function.

C Operators

10/11/2017 • 1 min to read • Edit Online

The C operators are a subset of the C++ built-in operators.

There are three types of operators. A unary expression consists of either a unary operator prepended to an operand, or the sizeof keyword followed by an expression. The expression can be either the name of a variable or a cast expression. If the expression is a cast expression, it must be enclosed in parentheses. A binary expression consists of two operands joined by a binary operator. A ternary expression consists of three operands joined by the conditional-expression operator.

C includes the following unary operators:

| SYMBOL | NAME |
|--------|---|
| -~! | Negation and complement operators |
| * & | Indirection and address-of operators |
| sizeof | Size operator |
| + | Unary plus operator |
| ++ | Unary increment and decrement operators |

Binary operators associate from left to right. C provides the following binary operators:

| SYMBOL | NAME |
|--------------|--------------------------------|
| * / % | Multiplicative operators |
| + - | Additive operators |
| << >> | Shift operators |
| < > <= >= != | Relational operators |
| & ^ | Bitwise operators |
| && | Logical operators |
| | Sequential-evaluation operator |

The base operator (:>), supported by previous versions of the Microsoft 16-bit C compiler, is described in C Language Syntax Summary.

The conditional-expression operator has lower precedence than binary expressions and differs from them in being right associative.

Expressions with operators also include assignment expressions, which use unary or binary assignment operators. The unary assignment operators are the increment (++) and decrement (--) operators; the binary assignment

operators are the simple-assignment operator (=) and the compound-assignment operators. Each compound-assignment operator is a combination of another binary operator with the simple-assignment operator.

Precedence and Order of Evaluation

10/11/2017 • 4 min to read • Edit Online

The precedence and associativity of C operators affect the grouping and evaluation of operands in expressions. An operator's precedence is meaningful only if other operators with higher or lower precedence are present. Expressions with higher-precedence operators are evaluated first. Precedence can also be described by the word "binding." Operators with a higher precedence are said to have tighter binding.

The following table summarizes the precedence and associativity (the order in which the operands are evaluated) of C operators, listing them in order of precedence from highest to lowest. Where several operators appear together, they have equal precedence and are evaluated according to their associativity. The operators in the table are described in the sections beginning with Postfix Operators. The rest of this section gives general information about precedence and associativity.

Precedence and Associativity of C Operators

| SYMBOL1 | TYPE OF OPERATION | ASSOCIATIVITY |
|--|------------------------|---------------|
| > postfix ++ and postfix | Expression | Left to right |
| prefix ++ and prefix sizeof & * + - ~! | Unary | Right to left |
| typecasts | Unary | Right to left |
| */% | Multiplicative | Left to right |
| + - | Additive | Left to right |
| << >> | Bitwise shift | Left to right |
| <><=>= | Relational | Left to right |
| ==!= | Equality | Left to right |
| 82 | Bitwise-AND | Left to right |
| ۸ | Bitwise-exclusive-OR | Left to right |
| I | Bitwise-inclusive-OR | Left to right |
| && | Logical-AND | Left to right |
| | Logical-OR | Left to right |
| ?: | Conditional-expression | Right to left |

| SYMBOL1 | TYPE OF OPERATION | ASSOCIATIVITY |
|-----------------|---------------------------------|---------------|
| = *= /= %= | Simple and compound assignment2 | Right to left |
| += -= <<= >>=&= | | |
| ^= = | | |
| | Sequential evaluation | Left to right |

- 1. Operators are listed in descending order of precedence. If several operators appear on the same line or in a group, they have equal precedence.
- 2. All simple and compound-assignment operators have equal precedence.

An expression can contain several operators with equal precedence. When several such operators appear at the same level in an expression, evaluation proceeds according to the associativity of the operator, either from right to left or from left to right. The direction of evaluation does not affect the results of expressions that include more than one multiplication (\mathbf{V}), addition (+), or binary-bitwise (& | ^*) operator at the same level. Order of operations is not defined by the language. The compiler is free to evaluate such expressions in any order, if the compiler can guarantee a consistent result.

Only the sequential-evaluation (,), logical-AND (&&), logical-OR (|||), conditional-expression (?:), and function-call operators constitute sequence points and therefore guarantee a particular order of evaluation for their operands. The function-call operator is the set of parentheses following the function identifier. The sequential-evaluation operator (,) is guaranteed to evaluate its operands from left to right. (Note that the comma operator in a function call is not the same as the sequential-evaluation operator and does not provide any such guarantee.) For more information, see Sequence Points.

Logical operators also guarantee evaluation of their operands from left to right. However, they evaluate the smallest number of operands needed to determine the result of the expression. This is called "short-circuit" evaluation. Thus, some operands of the expression may not be evaluated. For example, in the expression

```
x && y++
```

the second operand, y++, is evaluated only if x is true (nonzero). Thus, y is not incremented if x is false (0).

Examples

The following list shows how the compiler automatically binds several sample expressions:

| EXPRESSION | AUTOMATIC BINDING |
|-------------|-------------------|
| a & b c | (a & b) c |
| a = b c | a = (b c) |
| q && r s | (q && r) s |

In the first expression, the bitwise-AND operator () has higher precedence than the logical-OR operator (), so a & b forms the first operand of the logical-OR operation.

In the second expression, the logical-OR operator (| |) has higher precedence than the simple-assignment operator (=), so b | | c is grouped as the right-hand operand in the assignment. Note that the value assigned to a is either 0 or 1.

The third expression shows a correctly formed expression that may produce an unexpected result. The logical-AND operator (&&) has higher precedence than the logical-OR operator (|||), so ||q && r || is grouped as an operand. Since the logical operators guarantee evaluation of operands from left to right, ||q && r || is evaluated before ||s--|. However, if ||q && r || evaluates to a nonzero value, ||s--| is not evaluated, and ||s || is not decremented. If not decrementing ||s || would cause a problem in your program, ||s--| should appear as the first operand of the expression, or ||s || should be decremented in a separate operation.

The following expression is illegal and produces a diagnostic message at compile time:

| ILLEGAL EXPRESSION | DEFAULT GROUPING |
|-------------------------|------------------------------|
| p == 0 ? p += 1: p += 2 | (p == 0 ? p += 1 : p) += 2 |

In this expression, the equality operator (==) has the highest precedence, so p==0 is grouped as an operand. The conditional-expression operator (==) has the next-highest precedence. Its first operand is p==0, and its second operand is p+=1. However, the last operand of the conditional-expression operator is considered to be p rather than p+=2, since this occurrence of p binds more closely to the conditional-expression operator than it does to the compound-assignment operator. A syntax error occurs because p=2 does not have a left-hand operand. You should use parentheses to prevent errors of this kind and produce more readable code. For example, you could use parentheses as shown below to correct and clarify the preceding example:

```
( p == 0 ) ? ( p += 1 ) : ( p += 2 )
```

Usual Arithmetic Conversions

10/11/2017 • 2 min to read • Edit Online

Most C operators perform type conversions to bring the operands of an expression to a common type or to extend short values to the integer size used in machine operations. The conversions performed by C operators depend on the specific operator and the type of the operand or operands. However, many operators perform similar conversions on operands of integral and floating types. These conversions are known as "arithmetic conversions." Conversion of an operand value to a compatible type causes no change to its value.

The arithmetic conversions summarized below are called "usual arithmetic conversions." These steps are applied only for binary operators that expect arithmetic type. The purpose is to yield a common type which is also the type of the result. To determine which conversions actually take place, the compiler applies the following algorithm to binary operations in the expression. The steps below are not a precedence order.

- 1. If either operand is of type long double, the other operand is converted to type long double.
- 2. If the above condition is not met and either operand is of type **double**, the other operand is converted to type **double**.
- 3. If the above two conditions are not met and either operand is of type **float**, the other operand is converted to type **float**.
- 4. If the above three conditions are not met (none of the operands are of floating types), then integral conversions are performed on the operands as follows:
 - If either operand is of type unsigned long, the other operand is converted to type unsigned long.
 - If the above condition is not met and either operand is of type **long** and the other of type unsigned int , both operands are converted to type unsigned long.
 - If the above two conditions are not met, and either operand is of type long, the other operand is converted to type long.
 - If the above three conditions are not met, and either operand is of type unsigned int , the other operand is converted to type unsigned int .
 - If none of the above conditions are met, both operands are converted to type int.

The following code illustrates these conversion rules:

Postfix Operators

The postfix operators have the highest precedence (the tightest binding) in expression evaluation.

Syntax

```
postfix-expression:
primary-expression

postfix-expression [ expression ]

postfix-expression ( argument-expression-list opt)

postfix-expression . identifier

postfix-expression -> identifier

postfix-expression ++

postfix-expression --
```

Operators in this precedence level are the array subscripts, function calls, structure and union members, and postfix increment and decrement operators.

One-Dimensional Arrays

10/11/2017 • 2 min to read • Edit Online

A postfix expression followed by an expression in square brackets ([]) is a subscripted representation of an element of an array object. A subscript expression represents the value at the address that is *expression* positions beyond *postfix-expression* when expressed as

```
postfix-expression
[
expression
]
```

Usually, the value represented by *postfix-expression* is a pointer value, such as an array identifier, and *expression* is an integral value. However, all that is required syntactically is that one of the expressions be of pointer type and the other be of integral type. Thus the integral value could be in the *postfix-expression* position and the pointer value could be in the brackets in the *expression*, or "subscript," position. For example, this code is legal:

```
// one_dimensional_arrays.c
int sum, *ptr, a[10];
int main() {
   ptr = a;
   sum = 4[ptr];
}
```

Subscript expressions are generally used to refer to array elements, but you can apply a subscript to any pointer. Whatever the order of values, *expression* must be enclosed in brackets ([]).

The subscript expression is evaluated by adding the integral value to the pointer value, then applying the indirection operator (χ *) to the result. (See Indirection and Address-of Operators for a discussion of the indirection operator.) In effect, for a one-dimensional array, the following four expressions are equivalent, assuming that \bar{a} is a pointer and \bar{b} is an integer:

```
a[b]
*(a + b)
*(b + a)
b[a]
```

According to the conversion rules for the addition operator (given in Additive Operators), the integral value is converted to an address offset by multiplying it by the length of the type addressed by the pointer.

For example, suppose the identifier line refers to an array of int values. The following procedure is used to evaluate the subscript expression line[i]:

- 1. The integer value i is multiplied by the number of bytes defined as the length of an int item. The converted value of i represents i int positions.
- 2. This converted value is added to the original pointer value (line) to yield an address that is offset i int positions from line.
- 3. The indirection operator is applied to the new address. The result is the value of the array element at that position (intuitively, line [i]).

The subscript expression <code>line[0]</code> represents the value of the first element of line, since the offset from the address represented by <code>line</code> is 0. Similarly, an expression such as <code>line[5]</code> refers to the element offset five positions from line, or the sixth element of the array.

Multidimensional Arrays (C)

10/11/2017 • 2 min to read • Edit Online

A subscript expression can also have multiple subscripts, as follows:

```
expression1
[
expression2
] [
expression3
]...
```

Subscript expressions associate from left to right. The leftmost subscript expression, *expression1* [*expression2*], is evaluated first. The address that results from adding *expression1* and *expression2* forms a pointer expression; then *expression3* is added to this pointer expression to form a new pointer expression, and so on until the last subscript expression has been added. The indirection operator (\(\frac{1}{2}\)) is applied after the last subscripted expression is evaluated, unless the final pointer value addresses an array type (see examples below).

Expressions with multiple subscripts refer to elements of "multidimensional arrays." A multidimensional array is an array whose elements are arrays. For example, the first element of a three-dimensional array is an array with two dimensions.

Examples

For the following examples, an array named prop is declared with three elements, each of which is a 4-by-6 array of int values.

```
int prop[3][4][6];
int i, *ip, (*ipp)[6];
```

A reference to the prop array looks like this:

```
i = prop[0][0][1];
```

The example above shows how to refer to the second individual intelement of prop. Arrays are stored by row, so the last subscript varies most quickly; the expression prop[0][0][2] refers to the next (third) element of the array, and so on.

```
i = prop[2][1][3];
```

This statement is a more complex reference to an individual element of prop . The expression is evaluated as follows:

- 1. The first subscript, 2, is multiplied by the size of a 4-by-6 int array and added to the pointer value prop.

 The result points to the third 4-by-6 array of prop.
- 2. The second subscript, 1, is multiplied by the size of the 6-element int array and added to the address represented by prop[2].

- 3. Each element of the 6-element array is an int value, so the final subscript, 3, is multiplied by the size of an int before it is added to prop[2][1]. The resulting pointer addresses the fourth element of the 6-element array.
- 4. The indirection operator is applied to the pointer value. The result is the <code>int</code> element at that address.

These next two examples show cases where the indirection operator is not applied.

```
ip = prop[2][1];
ipp = prop[2];
```

In the first of these statements, the expression prop[2][1] is a valid reference to the three-dimensional array prop; it refers to a 6-element array (declared above). Since the pointer value addresses an array, the indirection operator is not applied.

Similarly, the result of the expression prop[2] in the second statement ipp = prop[2]; is a pointer value addressing a two-dimensional array.

Function Call (C)

10/11/2017 • 1 min to read • Edit Online

A "function call" is an expression that includes the name of the function being called or the value of a function pointer and, optionally, the arguments being passed to the function.

Syntax

postfix-expression:
postfix-expression (argument-expression-list opt)

argument-expression-list: assignment-expression

argument-expression-list, assignment-expression

The *postfix-expression* must evaluate to a function address (for example, a function identifier or the value of a function pointer), and *argument-expression-list* is a list of expressions (separated by commas) whose values (the "arguments") are passed to the function. The *argument-expression-list* argument can be empty.

A function-call expression has the value and type of the function's return value. A function cannot return an object of array type. If the function's return type is void (that is, the function has been declared never to return a value), the function-call expression also has void type. (See Function Calls for more information.)

Structure and Union Members

10/11/2017 • 1 min to read • Edit Online

A "member-selection expression" refers to members of structures and unions. Such an expression has the value and type of the selected member.

```
postfix-expression
.
identifier
postfix-expression
->
identifier
```

This list describes the two forms of the member-selection expressions:

- 1. In the first form, *postfix-expression* represents a value of struct or **union** type, and *identifier* names a member of the specified structure or union. The value of the operation is that of *identifier* and is an I-value if *postfix-expression* is an I-value. See L-Value and R-Value Expressions for more information.
- 2. In the second form, *postfix-expression* represents a pointer to a structure or union, and *identifier* names a member of the specified structure or union. The value is that of *identifier* and is an I-value.

The two forms of member-selection expressions have similar effects.

In fact, an expression involving the member-selection operator (->) is a shorthand version of an expression using the period (.) if the expression before the period consists of the indirection operator (χ^*) applied to a pointer value. Therefore,

```
expression
->
identifier
```

is equivalent to

```
(*
expression
) .
identifier
```

when expression is a pointer value.

Examples

The following examples refer to this structure declaration. For information about the indirection operator (χ^*) used in these examples, see Indirection and Address-of Operators.

```
struct pair
{
   int a;
   int b;
   struct pair *sp;
} item, list[10];
```

A member-selection expression for the <code>item</code> structure looks like this:

```
item.sp = &item;
```

In the example above, the address of the item structure is assigned to the sp member of the structure. This means that item contains a pointer to itself.

```
(item.sp)->a = 24;
```

In this example, the pointer expression item.sp is used with the member-selection operator (->) to assign a value to the member a.

```
list[8].b = 12;
```

This statement shows how to select an individual structure member from an array of structures.

C Postfix Increment and Decrement Operators

10/11/2017 • 1 min to read • Edit Online

Operands of the postfix increment and decrement operators are scalar types that are modifiable I-values.

Syntax

postfix-expression:
postfix-expression ++
postfix-expression --

The result of the postfix increment or decrement operation is the value of the operand. After the result is obtained, the value of the operand is incremented (or decremented). The following code illustrates the postfix increment operator.

```
if( var++ > 0 )
*p++ = *q++;
```

In this example, the variable var is compared to 0, then incremented. If var was positive before being incremented, the next statement is executed. First, the value of the object pointed to by q is assigned to the object pointed to by p. Then, q and p are incremented.

Prefix Increment and Decrement Operators

10/11/2017 • 1 min to read • Edit Online

The unary operators (++ and --) are called "prefix" increment or decrement operators when the increment or decrement operators appear before the operand. Postfix increment and decrement has higher precedence than prefix increment and decrement. The operand must have integral, floating, or pointer type and must be a modifiable l-value expression (an expression without the **const** attribute). The result is an l-value.

When the operator appears before its operand, the operand is incremented or decremented and its new value is the result of the expression.

An operand of integral or floating type is incremented or decremented by the integer value 1. The type of the result is the same as the operand type. An operand of pointer type is incremented or decremented by the size of the object it addresses. An incremented pointer points to the next object; a decremented pointer points to the previous object.

Example

This example illustrates the unary prefix decrement operator:

```
if( line[--i] != '\n' )
    return;
```

In this example, the variable i is decremented before it is used as a subscript to line.

Indirection and Address-of Operators

10/11/2017 • 2 min to read • Edit Online

The indirection operator (χ^*) accesses a value indirectly, through a pointer. The operand must be a pointer value. The result of the operation is the value addressed by the operand; that is, the value at the address to which its operand points. The type of the result is the type that the operand addresses.

If the operand points to a function, the result is a function designator. If it points to a storage location, the result is an I-value designating the storage location.

If the pointer value is invalid, the result is undefined. The following list includes some of the most common conditions that invalidate a pointer value.

- The pointer is a null pointer.
- The pointer specifies the address of a local item that is not visible at the time of the reference.
- The pointer specifies an address that is inappropriately aligned for the type of the object pointed to.
- The pointer specifies an address not used by the executing program.

The address-of operator (&) gives the address of its operand. The operand of the address-of operator can be either a function designator or an I-value that designates an object that is not a bit field and is not declared with the **register** storage-class specifier.

The result of the address operation is a pointer to the operand. The type addressed by the pointer is the type of the operand.

The address-of operator can only be applied to variables with fundamental, structure, or union types that are declared at the file-scope level, or to subscripted array references. In these expressions, a constant expression that does not include the address-of operator can be added to or subtracted from the address expression.

Examples

The following examples use these declarations:

```
int *pa, x;
int a[20];
double d;
```

This statement uses the address-of operator:

```
pa = &a[5];
```

The address-of operator (&) takes the address of the sixth element of the array a. The result is stored in the pointer variable pa.

```
x = *pa;
```

The indirection operator (χ^*) is used in this example to access the int value at the address stored in pa. The value is assigned to the integer variable χ .

```
if( x == *&x )
    printf( "True\n" );
```

This example prints the word T_{rue} , demonstrating that the result of applying the indirection operator to the address of x is the same as x.

```
int roundup( void );    /* Function declaration */
int *proundup = roundup;
int *pround = &roundup;
```

Once the function roundup is declared, two pointers to roundup are declared and initialized. The first pointer, proundup, is initialized using only the name of the function, while the second, pround, uses the address-of operator in the initialization. The initializations are equivalent.

Unary Arithmetic Operators

10/11/2017 • 1 min to read • Edit Online

The C unary plus, arithmetic-negation, complement, and logical-negation operators are discussed in the following list:

| OPERATOR | DESCRIPTION |
|----------|---|
| + | The unary plus operator preceding an expression in parentheses forces the grouping of the enclosed operations. It is used with expressions involving more than one associative or commutative binary operator. The operand must have arithmetic type. The result is the value of the operand. An integral operand undergoes integral promotion. The type of the result is the type of the promoted operand. |
| - | The arithmetic-negation operator produces the negative (two's complement) of its operand. The operand must be an integral or floating value. This operator performs the usual arithmetic conversions. |
| ~ | The bitwise-complement (or bitwise-NOT) operator produces the bitwise complement of its operand. The operand must be of integral type. This operator performs usual arithmetic conversions; the result has the type of the operand after conversion. |
| ! | The logical-negation (logical-NOT) operator produces the value 0 if its operand is true (nonzero) and the value 1 if its operand is false (0). The result has int type. The operand must be an integral, floating, or pointer value. |

Unary arithmetic operations on pointers are illegal.

Examples

The following examples illustrate the unary arithmetic operators:

```
short x = 987;
x = -x;
```

In the example above, the new value of x is the negative of 987, or -987.

```
unsigned short y = 0xAAAA;
y = ~y;
```

In this example, the new value assigned to y is the one's complement of the unsigned value 0xAAAA, or 0x5555.

```
if( !(x < y) )
```

If x is greater than or equal to y, the result of the expression is 1 (true). If x is less than y, the result is 0 (false).

sizeof Operator (C)

10/11/2017 • 1 min to read • Edit Online

The sizeof operator gives the amount of storage, in bytes, required to store an object of the type of the operand. This operator allows you to avoid specifying machine-dependent data sizes in your programs.

Syntax

```
sizeof unary-expression
sizeof ( type-name )
```

Remarks

The operand is either an identifier that is a *unary-expression*, or a type-cast expression (that is, a type specifier enclosed in parentheses). The *unary-expression* cannot represent a bit-field object, an incomplete type, or a function designator. The result is an unsigned integral constant. The standard header STDDEF.H defines this type as **size_t**.

When you apply the sizeof operator to an array identifier, the result is the size of the entire array rather than the size of the pointer represented by the array identifier.

When you apply the sizeof operator to a structure or union type name, or to an identifier of structure or union type, the result is the number of bytes in the structure or union, including internal and trailing padding. This size may include internal and trailing padding used to align the members of the structure or union on memory boundaries. Thus, the result may not correspond to the size calculated by adding up the storage requirements of the individual members.

If an unsized array is the last element of a structure, the size of the structure without the array.

```
buffer = calloc(100, sizeof (int) );
```

This example uses the size of operator to pass the size of an int, which varies among machines, as an argument to a run-time function named calloc. The value returned by the function is stored in buffer.

```
static char *strings[] = {
    "this is string one",
    "this is string two",
    "this is string three",
    };
const int string_no = ( sizeof strings ) / ( sizeof strings[0] );
```

In this example, strings is an array of pointers to char. The number of pointers is the number of elements in the array, but is not specified. It is easy to determine the number of pointers by using the sizeof operator to calculate the number of elements in the array. The **const** integer value string_no is initialized to this number. Because it is a **const** value, string_no cannot be modified.

Cast Operators

10/11/2017 • 1 min to read • Edit Online

A type cast provides a method for explicit conversion of the type of an object in a specific situation.

Syntax

cast-expression: unary-expression

(type-name) cast-expression

The compiler treats *cast-expression* as type *type-name* after a type cast has been made. Casts can be used to convert objects of any scalar type to or from any other scalar type. Explicit type casts are constrained by the same rules that determine the effects of implicit conversions, discussed in Assignment Conversions. Additional restraints on casts may result from the actual sizes or representation of specific types. See Storage of Basic Types for information on actual sizes of integral types. For more information on type casts, see Type-Cast Conversions.

C Multiplicative Operators

10/11/2017 • 2 min to read • Edit Online

The multiplicative operators perform multiplication (\backslash), division (/*), and remainder (/*) operations.

Syntax

multiplicative-expression: cast-expression

multiplicative-expression * cast-expression

multiplicative-expression / cast-expression

multiplicative-expression % cast-expression

The operands of the remainder operator (%) must be integral. The multiplication (\bigvee and division (/*) operators can take integral- or floating-type operands; the types of the operands can be different.

The multiplicative operators perform the usual arithmetic conversions on the operands. The type of the result is the type of the operands after conversion.

NOTE

Since the conversions performed by the multiplicative operators do not provide for overflow or underflow conditions, information may be lost if the result of a multiplicative operation cannot be represented in the type of the operands after conversion.

The C multiplicative operators are described below:

| OPERATOR | DESCRIPTION |
|------------|--|
| \ * | The multiplication operator causes its two operands to be multiplied. |
| / | The division operator causes the first operand to be divided by the second. If two integer operands are divided and the result is not an integer, it is truncated according to the following rules: |
| | - The result of division by 0 is undefined according to the ANSI C standard. The Microsoft C compiler generates an error at compile time or run time. |
| | - If both operands are positive or unsigned, the result is truncated toward 0. |
| | - If either operand is negative, whether the result of the operation is the largest integer less than or equal to the algebraic quotient or is the smallest integer greater than or equal to the algebraic quotient is implementation defined. (See the Microsoft Specific section below.) |

| OPERATOR | DESCRIPTION |
|----------|---|
| % | The result of the remainder operator is the remainder when the first operand is divided by the second. When the division is inexact, the result is determined by the following rules: |
| | - If the right operand is zero, the result is undefined. |
| | - If both operands are positive or unsigned, the result is positive. |
| | - If either operand is negative and the result is inexact, the result is implementation defined. (See the Microsoft Specific section below.) |

Microsoft Specific

In division where either operand is negative, the direction of truncation is toward 0.

If either operation is negative in division with the remainder operator, the result has the same sign as the dividend (the first operand in the expression).

END Microsoft Specific

Examples

The declarations shown below are used for the following examples:

```
int i = 10, j = 3, n;
double x = 2.0, y;
```

This statement uses the multiplication operator:

```
y = x * i;
```

In this case, x is multiplied by i to give the value 20.0. The result has **double** type.

```
n = i / j;
```

In this example, 10 is divided by 3. The result is truncated toward 0, yielding the integer value 3.

```
n = i % j;
```

This statement assigns n the integer remainder, 1, when 10 is divided by 3.

Microsoft Specific

The sign of the remainder is the same as the sign of the dividend. For example:

```
50 % -6 = 2
-50 % 6 = -2
```

In each case, 50 and 2 have the same sign.

C Additive Operators

10/11/2017 • 1 min to read • Edit Online

The additive operators perform addition (+) and subtraction (-).

Syntax

additive-expression: multiplicative-expression

additive-expression + multiplicative-expression

additive-expression - multiplicative-expression

NOTE

Although the syntax for *additive-expression* includes *multiplicative-expression*, this does not imply that expressions using multiplication are required. See the syntax in C Language Syntax Summary, for *multiplicative-expression*, *cast-expression*, and *unary-expression*.

The operands can be integral or floating values. Some additive operations can also be performed on pointer values, as outlined under the discussion of each operator.

The additive operators perform the usual arithmetic conversions on integral and floating operands. The type of the result is the type of the operands after conversion. Since the conversions performed by the additive operators do not provide for overflow or underflow conditions, information may be lost if the result of an additive operation cannot be represented in the type of the operands after conversion.

Addition (+)

10/11/2017 • 1 min to read • Edit Online

The addition operator (+) causes its two operands to be added. Both operands can be either integral or floating types, or one operand can be a pointer and the other an integer.

When an integer is added to a pointer, the integer value (*i*) is converted by multiplying it by the size of the value that the pointer addresses. After conversion, the integer value represents *i* memory positions, where each position has the length specified by the pointer type. When the converted integer value is added to the pointer value, the result is a new pointer value representing the address *i* positions from the original address. The new pointer value addresses a value of the same type as the original pointer value and therefore is the same as array indexing (see One-Dimensional Arrays and Multidimensional Arrays). If the sum pointer points outside the array, except at the first location beyond the high end, the result is undefined. For more information, see Pointer Arithmetic.

See Also

Subtraction (-)

10/11/2017 • 1 min to read • Edit Online

The subtraction operator (-) subtracts the second operand from the first. Both operands can be either integral or floating types, or one operand can be a pointer and the other an integer.

When two pointers are subtracted, the difference is converted to a signed integral value by dividing the difference by the size of a value of the type that the pointers address. The size of the integral value is defined by the type **ptrdiff_t** in the standard include file STDDEF.H. The result represents the number of memory positions of that type between the two addresses. The result is only guaranteed to be meaningful for two elements of the same array, as discussed in Pointer Arithmetic.

When an integer value is subtracted from a pointer value, the subtraction operator converts the integer value (i) by multiplying it by the size of the value that the pointer addresses. After conversion, the integer value represents i memory positions, where each position has the length specified by the pointer type. When the converted integer value is subtracted from the pointer value, the result is the memory address i positions before the original address. The new pointer points to a value of the type addressed by the original pointer value.

Using the Additive Operators

10/11/2017 • 1 min to read • Edit Online

The following examples, which illustrate the addition and subtraction operators, use these declarations:

```
int i = 4, j;
float x[10];
float *px;
```

These statements are equivalent:

```
px = &x[4 + i];
px = &x[4] + i;
```

The value of i is multiplied by the length of a **float** and added to x = 1. The resulting pointer value is the address of x = 1.

```
j = &x[i] - &x[i-2];
```

In this example, the address of the third element of x (given by x[i-2]) is subtracted from the address of the fifth element of x (given by x[i]). The difference is divided by the length of a **float**; the result is the integer value 2.

Pointer Arithmetic

10/11/2017 • 1 min to read • Edit Online

Additive operations involving a pointer and an integer give meaningful results only if the pointer operand addresses an array member and the integer value produces an offset within the bounds of the same array. When the integer value is converted to an address offset, the compiler assumes that only memory positions of the same size lie between the original address and the address plus the offset.

This assumption is valid for array members. By definition, an array is a series of values of the same type; its elements reside in contiguous memory locations. However, storage for any types except array elements is not guaranteed to be filled by the same type of identifiers. That is, blanks can appear between memory positions, even positions of the same type. Therefore, the results of adding to or subtracting from the addresses of any values but array elements are undefined.

Similarly, when two pointer values are subtracted, the conversion assumes that only values of the same type, with no blanks, lie between the addresses given by the operands.

Bitwise Shift Operators

10/11/2017 • 1 min to read • Edit Online

The shift operators shift their first operand left (<<) or right (>>) by the number of positions the second operand specifies.

Syntax

shift-expression: additive-expression

shift-expression << additive-expression shift-expression >> additive-expression

Both operands must be integral values. These operators perform the usual arithmetic conversions; the type of the result is the type of the left operand after conversion.

For leftward shifts, the vacated right bits are set to 0. For rightward shifts, the vacated left bits are filled based on the type of the first operand after conversion. If the type is unsigned, they are set to 0. Otherwise, they are filled with copies of the sign bit. For left-shift operators without overflow, the statement

```
expr1 << expr2
```

is equivalent to multiplication by 2^{expr2}. For right-shift operators,

```
expr1 >> expr2
```

is equivalent to division by 2 expr2 if expr1 is unsigned or has a nonnegative value.

The result of a shift operation is undefined if the second operand is negative, or if the right operand is greater than or equal to the width in bits of the promoted left operand.

Since the conversions performed by the shift operators do not provide for overflow or underflow conditions, information may be lost if the result of a shift operation cannot be represented in the type of the first operand after conversion.

```
unsigned int x, y, z;

x = 0x00AA;
y = 0x5500;

z = ( x << 8 ) + ( y >> 8 );
```

In this example, x is shifted left eight positions and y is shifted right eight positions. The shifted values are added, giving 0xAA55, and assigned to z.

Shifting a negative value to the right yields half the original value, rounded down. For example, -253 (binary 11111111 00000011) shifted right one bit produces -127 (binary 11111111 10000001). A positive 253 shifts right to produce +126.

Right shifts preserve the sign bit. When a signed integer shifts right, the most-significant bit remains set. When an unsigned integer shifts right, the most-significant bit is cleared.

C Relational and Equality Operators

10/11/2017 • 3 min to read • Edit Online

The binary relational and equality operators compare their first operand to their second operand to test the validity of the specified relationship. The result of a relational expression is 1 if the tested relationship is true and 0 if it is false. The type of the result is int.

Syntax

relational-expression:
shift-expression
relational-expression < shift-expression
relational-expression > shift-expression
relational-expression <= shift-expression
relational-expression >= shift-expression
equality-expression:
relational-expression
equality-expression == relational-expression
equality-expression!= relational-expression

The relational and equality operators test the following relationships:

| OPERATOR | RELATIONSHIP TESTED |
|----------|---|
| < | First operand less than second operand |
| > | First operand greater than second operand |
| <= | First operand less than or equal to second operand |
| >= | First operand greater than or equal to second operand |
| == | First operand equal to second operand |
| != | First operand not equal to second operand |

The first four operators in the list above have a higher precedence than the equality operators (== and !=). See the precedence information in the table Precedence and Associativity of C Operators.

The operands can have integral, floating, or pointer type. The types of the operands can be different. Relational operators perform the usual arithmetic conversions on integral and floating type operands. In addition, you can use the following combinations of operand types with the relational and equality operators:

• Both operands of any relational or equality operator can be pointers to the same type. For the equality (==) and inequality (!=) operators, the result of the comparison indicates whether the two pointers address the same memory location. For the other relational operators (<, >, <=, and >=), the result of the comparison indicates the relative position of the two memory addresses of the objects pointed to. Relational operators

compare only offsets.

Pointer comparison is defined only for parts of the same object. If the pointers refer to members of an array, the comparison is equivalent to comparison of the corresponding subscripts. The address of the first array element is "less than" the address of the last element. In the case of structures, pointers to structure members declared later are "greater than" pointers to members declared earlier in the structure. Pointers to the members of the same union are equal.

- A pointer value can be compared to the constant value 0 for equality (==) or inequality (!=). A pointer with a value of 0 is called a "null" pointer; that is, it does not point to a valid memory location.
- The equality operators follow the same rules as the relational operators, but permit additional possibilities: a pointer can be compared to a constant integral expression with value 0, or to a pointer to void. If two pointers are both null pointers, they compare as equal. Equality operators compare both segment and offset.

Examples

The examples below illustrate relational and equality operators.

```
int x = 0, y = 0;
if ( x < y )</pre>
```

Because x and y are equal, the expression in this example yields the value 0.

```
char array[10];
char *p;

for ( p = array; p < &array[10]; p++ )
    *p = '\0';</pre>
```

The fragment in this example sets each element of array to a null character constant.

```
enum color { red, white, green } col;
.
.
.
.
if ( col == red )
.
.
.
```

These statements declare an enumeration variable named col with the tag color. At any time, the variable may contain an integer value of 0, 1, or 2, which represents one of the elements of the enumeration set color the color red, white, or green, respectively. If col contains 0 when the **if** statement is executed, any statements depending on the **if** will be executed.

C Bitwise Operators

The bitwise operators perform bitwise-AND (&), bitwise-exclusive-OR (^), and bitwise-inclusive-OR (|) operations.

Syntax

```
AND-expression:
equality-expression

AND-expression & equality-expression

exclusive-OR-expression:
AND-expression

exclusive-OR-expression ^ AND-expression

inclusive-OR-expression:
exclusive-OR-expression:
```

inclusive-OR-expression | exclusive-OR-expression

The operands of bitwise operators must have integral types, but their types can be different. These operators perform the usual arithmetic conversions; the type of the result is the type of the operands after conversion.

The C bitwise operators are described below:

| OPERATOR | DESCRIPTION |
|----------|---|
| & | The bitwise-AND operator compares each bit of its first operand to the corresponding bit of its second operand. If both bits are 1, the corresponding result bit is set to 1. Otherwise, the corresponding result bit is set to 0. |
| ^ | The bitwise-exclusive-OR operator compares each bit of its first operand to the corresponding bit of its second operand. If one bit is 0 and the other bit is 1, the corresponding result bit is set to 1. Otherwise, the corresponding result bit is set to 0. |
| I | The bitwise-inclusive-OR operator compares each bit of its first operand to the corresponding bit of its second operand. If either bit is 1, the corresponding result bit is set to 1. Otherwise, the corresponding result bit is set to 0. |

Examples

These declarations are used for the following three examples:

```
short i = 0xAB00;
short j = 0xABCD;
short n;
n = i & j;
```

The result assigned to n in this first example is the same as i (0xAB00 hexadecimal).

```
n = i | j;
n = i ^ j;
```

The bitwise-inclusive OR in the second example results in the value 0xABCD (hexadecimal), while the bitwise-exclusive OR in the third example produces 0xCD (hexadecimal).

Microsoft Specific

The results of bitwise operation on signed integers is implementation-defined according to the ANSI C standard. For the Microsoft C compiler, bitwise operations on signed integers work the same as bitwise operations on unsigned integers. For example, -16 & 99 can be expressed in binary as

The result of the bitwise AND is 96 decimal.

C Logical Operators

10/11/2017 • 1 min to read • Edit Online

The logical operators perform logical-AND (&&) and logical-OR (| | |) operations.

Syntax

logical-AND-expression: inclusive-OR-expression

logical-AND-expression && inclusive-OR-expression

logical-OR-expression: logical-AND-expression

logical-OR-expression | logical-AND-expression

Logical operators do not perform the usual arithmetic conversions. Instead, they evaluate each operand in terms of its equivalence to 0. The result of a logical operation is either 0 or 1. The result's type is int.

The C logical operators are described below:

| OPERATOR | DESCRIPTION |
|----------|--|
| 8.8. | The logical-AND operator produces the value 1 if both operands have nonzero values. If either operand is equal to 0, the result is 0. If the first operand of a logical-AND operation is equal to 0, the second operand is not evaluated. |
| | The logical-OR operator performs an inclusive-OR operation on its operands. The result is 0 if both operands have 0 values. If either operand has a nonzero value, the result is 1. If the first operand of a logical-OR operation has a nonzero value, the second operand is not evaluated. |

The operands of logical-AND and logical-OR expressions are evaluated from left to right. If the value of the first operand is sufficient to determine the result of the operation, the second operand is not evaluated. This is called "short-circuit evaluation." There is a sequence point after the first operand. See Sequence Points for more information.

Examples

The following examples illustrate the logical operators:

```
int w, x, y, z;
if ( x < y && y < z )
    printf( "x is less than z\n" );</pre>
```

In this example, the printf function is called to print a message if x is less than y and y is less than z. If x is greater than y, the second operand (y < z) is not evaluated and nothing is printed. Note that this could cause problems in cases where the second operand has side effects that are being relied on for some other reason.

```
printf( "%d" , (x == w || x == y || x == z) );
```

In this example, if x is equal to either w, y, or z, the second argument to the printf function evaluates to true and the value 1 is printed. Otherwise, it evaluates to false and the value 0 is printed. As soon as one of the conditions evaluates to true, evaluation ceases.

Conditional-Expression Operator

10/11/2017 • 2 min to read • Edit Online

C has one ternary operator: the conditional-expression operator (?:).

Syntax

conditional-expression:

logical-OR-expression

logical-OR expression? expression: conditional-expression

The *logical-OR-expression* must have integral, floating, or pointer type. It is evaluated in terms of its equivalence to 0. A sequence point follows *logical-OR-expression*. Evaluation of the operands proceeds as follows:

- If logical-OR-expression is not equal to 0, expression is evaluated. The result of evaluating the expression is given by the nonterminal expression. (This means expression is evaluated only if logical-OR-expression is true.)
- If logical-OR-expression equals 0, conditional-expression is evaluated. The result of the expression is the value of conditional-expression. (This means conditional-expression is evaluated only if logical-OR-expression is false.)

Note that either expression or conditional-expression is evaluated, but not both.

The type of the result of a conditional operation depends on the type of the *expression* or *conditional-expression* operand, as follows:

- If expression or conditional-expression has integral or floating type (their types can be different), the operator performs the usual arithmetic conversions. The type of the result is the type of the operands after conversion.
- If both *expression* and *conditional-expression* have the same structure, union, or pointer type, the type of the result is the same structure, union, or pointer type.
- If both operands have type void, the result has type void.
- If either operand is a pointer to an object of any type, and the other operand is a pointer to void, the pointer to the object is converted to a pointer to void and the result is a pointer to void.
- If either *expression* or *conditional-expression* is a pointer and the other operand is a constant expression with the value 0, the type of the result is the pointer type.

In the type comparison for pointers, any type qualifiers (**const** or volatile) in the type to which the pointer points are insignificant, but the result type inherits the qualifiers from both components of the conditional.

Examples

The following examples show uses of the conditional operator:

```
j = ( i < 0 ) ? ( -i ) : ( i );
```

This example assigns the absolute value of i to j. If i is less than 0, -i is assigned to j. If i is greater than or equal to 0, i is assigned to j.

```
void f1( void );
void f2( void );
int x;
int y;
    .
    .
    ( x == y ) ? ( f1() ) : ( f2() );
```

In this example, two functions, f1 and f2, and two variables, x and y, are declared. Later in the program, if the two variables have the same value, the function f1 is called. Otherwise, f2 is called.

C Assignment Operators

10/11/2017 • 1 min to read • Edit Online

An assignment operation assigns the value of the right-hand operand to the storage location named by the left-hand operand. Therefore, the left-hand operand of an assignment operation must be a modifiable l-value. After the assignment, an assignment expression has the value of the left operand but is not an l-value.

Syntax

assignment-expression: conditional-expression

unary-expression assignment-operator assignment-expression

assignment-operator: one of
= *= /= %= += -= <<= >>= &= ^= |=

The assignment operators in C can both transform and assign values in a single operation. C provides the following assignment operators:

| OPERATOR | OPERATION PERFORMED |
|----------|---------------------------------|
| = | Simple assignment |
| *= | Multiplication assignment |
| /= | Division assignment |
| %= | Remainder assignment |
| += | Addition assignment |
| -= | Subtraction assignment |
| <<= | Left-shift assignment |
| >>= | Right-shift assignment |
| &= | Bitwise-AND assignment |
| ^= | Bitwise-exclusive-OR assignment |
| = | Bitwise-inclusive-OR assignment |

In assignment, the type of the right-hand value is converted to the type of the left-hand value, and the value is stored in the left operand after the assignment has taken place. The left operand must not be an array, a function, or a constant. The specific conversion path, which depends on the two types, is outlined in detail in Type Conversions.

The simple-assignment operator assigns its right operand to its left operand. The value of the right operand is converted to the type of the assignment expression and replaces the value stored in the object designated by the left operand. The conversion rules for assignment apply (see Assignment Conversions).

```
double x;
int y;
x = y;
```

In this example, the value of y is converted to type **double** and assigned to x.

C Compound Assignment

10/11/2017 • 1 min to read • Edit Online

The compound-assignment operators combine the simple-assignment operator with another binary operator. Compound-assignment operators perform the operation specified by the additional operator, then assign the result to the left operand. For example, a compound-assignment expression such as

```
expression1
+=
expression2
```

can be understood as

```
expression1
=
expression1
+
expression2
```

However, the compound-assignment expression is not equivalent to the expanded version because the compound-assignment expression evaluates *expression1* only once, while the expanded version evaluates *expression1* twice: in the addition operation and in the assignment operation.

The operands of a compound-assignment operator must be of integral or floating type. Each compound-assignment operator performs the conversions that the corresponding binary operator performs and restricts the types of its operands accordingly. The addition-assignment (+=) and subtraction-assignment (-=) operators can also have a left operand of pointer type, in which case the right-hand operand must be of integral type. The result of a compound-assignment operation has the value and type of the left operand.

```
#define MASK 0xff00

n &= MASK;
```

In this example, a bitwise-inclusive-AND operation is performed on n and MASK, and the result is assigned to n.

The manifest constant MASK is defined with a #define preprocessor directive.

Sequential-Evaluation Operator

10/11/2017 • 1 min to read • Edit Online

The sequential-evaluation operator, also called the "comma operator," evaluates its two operands sequentially from left to right.

Syntax

expression: assignment-expression

expression, assignment-expression

The left operand of the sequential-evaluation operator is evaluated as a void expression. The result of the operation has the same value and type as the right operand. Each operand can be of any type. The sequential-evaluation operator does not perform type conversions between its operands, and it does not yield an I-value. There is a sequence point after the first operand, which means all side effects from the evaluation of the left operand are completed before beginning evaluation of the right operand. See Sequence Points for more information.

The sequential-evaluation operator is typically used to evaluate two or more expressions in contexts where only one expression is allowed.

Commas can be used as separators in some contexts. However, you must be careful not to confuse the use of the comma as a separator with its use as an operator; the two uses are completely different.

Example

This example illustrates the sequential-evaluation operator:

```
for ( i = j = 1; i + j < 20; i += i, j-- );
```

In this example, each operand of the **for** statement's third expression is evaluated independently. The left operand i += i is evaluated first; then the right operand, j--, is evaluated.

```
func_one( x, y + 2, z );
func_two( (x--, y + 2), z );
```

In the function call to func_one, three arguments, separated by commas, are passed: x, y + 2, and z. In the function call to func_two, parentheses force the compiler to interpret the first comma as the sequential-evaluation operator. This function call passes two arguments to func_two. The first argument is the result of the sequential-evaluation operation (x--, y + 2), which has the value and type of the expression y + 2; the second argument is z.

Type Conversions (C)

10/11/2017 • 1 min to read • Edit Online

Type conversions depend on the specified operator and the type of the operand or operators. Type conversions are performed in the following cases:

- When a value of one type is assigned to a variable of a different type or an operator converts the type of its operand or operands before performing an operation
- When a value of one type is explicitly cast to a different type
- When a value is passed as an argument to a function or when a type is returned from a function

A character, a short integer, or an integer bit field, all either signed or not, or an object of enumeration type, can be used in an expression wherever an integer can be used. If an int can represent all the values of the original type, then the value is converted to int; otherwise, it is converted to unsigned int. This process is called "integral promotion." Integral promotions preserve value. That is, the value after promotion is guaranteed to be the same as before the promotion. See Usual Arithmetic Conversions for more information.

Assignment Conversions

10/11/2017 • 1 min to read • Edit Online

In assignment operations, the type of the value being assigned is converted to the type of the variable that receives the assignment. C allows conversions by assignment between integral and floating types, even if information is lost in the conversion. The conversion method used depends on the types involved in the assignment, as described in Usual Arithmetic Conversions and in the following sections:

- Conversions from Signed Integral Types
- Conversions from Unsigned Integral Types
- Conversions from Floating-Point Types
- Conversions to and from Pointer Types
- Conversions from Other Types

Type qualifiers do not affect the allowability of the conversion although a **const** l-value cannot be used on the left side of the assignment.

When a signed integer is converted to an unsigned integer with equal or greater size and the value of the signed integer is not negative, the value is unchanged. The conversion is made by sign-extending the signed integer. A signed integer is converted to a shorter signed integer by truncating the high-order bits. The result is interpreted as an unsigned value, as shown in this example.

```
int i = -3;
unsigned short u;

u = i;
printf_s( "%hu\n", u ); // Prints 65533
```

No information is lost when a signed integer is converted to a floating value, except that some precision may be lost when a **long int** or **unsigned long int** value is converted to a **float** value.

The following table summarizes conversions from signed integral types. This table assumes that the **char** type is signed by default. If you use a compile-time option to change the default for the **char** type to unsigned, the conversions given in the Conversions from Unsigned Integral Types table for the **unsigned char** type apply instead of the conversions in the following table, Conversions from Signed Integral Types.

Conversions from Unsigned Integral Types

10/11/2017 • 2 min to read • Edit Online

An unsigned integer is converted to a shorter unsigned or signed integer by truncating the high-order bits, or to a longer unsigned or signed integer by zero-extending (see the Conversions from Unsigned Integral Types table).

When the value with integral type is demoted to a signed integer with smaller size, or an unsigned integer is converted to its corresponding signed integer, the value is unchanged if it can be represented in the new type. However, the value it represents changes if the sign bit is set, as in the following example.

```
int j;
unsigned short k = 65533;

j = k;
printf_s( "%hd\n", j );  // Prints -3
```

If it cannot be represented, the result is implementation-defined. See Type-Cast Conversions for information on the Microsoft C compiler's handling of demotion of integers. The same behavior results from integer conversion or from type casting the integer.

Unsigned values are converted in a way that preserves their value and is not representable directly in C. The only exception is a conversion from unsigned long to **float**, which loses at most the low-order bits. Otherwise, value is preserved, signed or unsigned. When a value of integral type is converted to floating, and the value is outside the range representable, the result is undefined. (See Storage of Basic Types for information about the range for integral and floating-point types.)

The following table summarizes conversions from unsigned integral types.

Conversions from Unsigned Integral Types

Microsoft Specific

For the Microsoft 32-bit C compiler, the unsigned int type is equivalent to the unsigned long type. Conversion of an unsigned int value proceeds in the same way as conversion of an unsigned long. Conversions from unsigned long values to **float** are not accurate if the value being converted is larger than the maximum positive signed **long** value.

Conversions from Floating-Point Types

10/11/2017 • 2 min to read • Edit Online

A **float** value converted to a **double** or long double, or a **double** converted to a long double, undergoes no change in value. A **double** value converted to a **float** value is represented exactly, if possible. Precision may be lost if the value cannot be represented exactly. If the result is out of range, the behavior is undefined. See Limits on Floating-Point Constants for the range of floating-point types.

A floating value is converted to an integral value by first converting to a **long**, then from the **long** value to the specific integral value. The decimal portion of the floating value is discarded in the conversion to a **long**. If the result is still too large to fit into a **long**, the result of the conversion is undefined.

Microsoft Specific

When converting a **double** or long double floating-point number to a smaller floating-point number, the value of the floating-point variable is truncated toward zero when an underflow occurs. An overflow causes a run-time error. Note that the Microsoft C compiler maps long double to type **double**.

Conversions to and from Pointer Types

10/11/2017 • 2 min to read • Edit Online

A pointer to one type of value can be converted to a pointer to a different type. However, the result may be undefined because of the alignment requirements and sizes of different types in storage. A pointer to an object can be converted to a pointer to an object whose type requires less or equally strict storage alignment, and back again without change.

A pointer to void can be converted to or from a pointer to any type, without restriction or loss of information. If the result is converted back to the original type, the original pointer is recovered.

If a pointer is converted to another pointer with the same type but having different or additional qualifiers, the new pointer is the same as the old except for restrictions imposed by the new qualifier.

A pointer value can also be converted to an integral value. The conversion path depends on the size of the pointer and the size of the integral type, according to the following rules:

- If the size of the pointer is greater than or equal to the size of the integral type, the pointer behaves like an unsigned value in the conversion, except that it cannot be converted to a floating value.
- If the pointer is smaller than the integral type, the pointer is first converted to a pointer with the same size as the integral type, then converted to the integral type.

Conversely, an integral type can be converted to a pointer type according to the following rules:

- If the integral type is the same size as the pointer type, the conversion simply causes the integral value to be treated as a pointer (an unsigned integer).
- If the size of the integral type is different from the size of the pointer type, the integral type is first converted to the size of the pointer, using the conversion paths given in the tables Conversion from Signed Integral Types and Conversion from Unsigned Integral Types. It is then treated as a pointer value.

An integral constant expression with value 0 or such an expression cast to type **void** * can be converted by a type cast, by assignment, or by comparison to a pointer of any type. This produces a null pointer that is equal to another null pointer of the same type, but this null pointer is not equal to any pointer to a function or to an object. Integers other than the constant 0 can be converted to pointer type, but the result is not portable.

Conversions from Other Types

Since an enum value is an int value by definition, conversions to and from an enum value are the same as those for the int type. For the Microsoft C compiler, an integer is the same as a **long**.

Microsoft Specific

No conversions between structure or union types are allowed.

Any value can be converted to type void, but the result of such a conversion can be used only in a context where an expression value is discarded, such as in an expression statement.

The void type has no value, by definition. Therefore, it cannot be converted to any other type, and other types cannot be converted to void by assignment. However, you can explicitly cast a value to type void, as discussed in Type-Cast Conversions.

Type-Cast Conversions

10/11/2017 • 1 min to read • Edit Online

You can use type casts to explicitly convert types.

Syntax

cast-expression: unary expression

(type-name) cast-expression

type-name:

specifier-qualifier-list abstract-declarator opt

The *type-name* is a type and *cast-expression* is a value to be converted to that type. An expression with a type cast is not an I-value. The *cast-expression* is converted as though it had been assigned to a variable of type *type-name*. The conversion rules for assignments (outlined in Assignment Conversions) apply to type casts as well. The following table shows the types that can be cast to any given type.

Legal Type Casts

| DESTINATION TYPES | POTENTIAL SOURCES |
|---|--|
| Integral types | Any integer type or floating-point type, or pointer to an object |
| Floating-point | Any arithmetic type |
| A pointer to an object, or (void *) | Any integer type, (void *), a pointer to an object, or a function pointer |
| Function pointer | Any integral type, a pointer to an object, or a function pointer |
| A structure, union, or array | None |
| Void type | Any type |

Any identifier can be cast to void type. However, if the type specified in a type-cast expression is not void, then the identifier being cast to that type cannot be a void expression. Any expression can be cast to void, but an expression of type void cannot be cast to any other type. For example, a function with void return type cannot have its return cast to another type.

Note that a **void** * expression has a type pointer to void, not type void. If an object is cast to void type, the resulting expression cannot be assigned to any item. Similarly, a type-cast object is not an acceptable I-value, so no assignment can be made to a type-cast object.

Microsoft Specific

A type cast can be an I-value expression as long as the size of the identifier does not change. For information on I-value expressions, see L-Value and R-Value Expressions.

END Microsoft Specific

You can convert an expression to type void with a cast, but the resulting expression can be used only where a value is not required. An object pointer converted to **void** * and back to the original type will return to its original value.

Function-Call Conversions

10/11/2017 • 1 min to read • Edit Online

The type of conversion performed on the arguments in a function call depends on the presence of a function prototype (forward declaration) with declared argument types for the called function.

If a function prototype is present and includes declared argument types, the compiler performs type checking (see Functions).

If no function prototype is present, only the usual arithmetic conversions are performed on the arguments in the function call. These conversions are performed independently on each argument in the call. This means that a **float** value is converted to a **double**; a char or **short** value is converted to an int; and an unsigned char or **unsigned** short is converted to an unsigned int.

Statements (C)

10/11/2017 • 1 min to read • Edit Online

The statements of a C program control the flow of program execution. In C, as in other programming languages, several kinds of statements are available to perform loops, to select other statements to be executed, and to transfer control. Following a brief overview of statement syntax, this section describes the C statements in alphabetical order:

| break statement | if statement |
|-----------------------------|-----------------------|
| compound statement | null statement |
| continue statement | return statement |
| do-while statement | switch statement |
| expression statement | try-except statement |
| for statement | try-finally statement |
| goto and labeled statements | while statement |

Overview of C Statements

10/11/2017 • 1 min to read • Edit Online

C statements consist of tokens, expressions, and other statements. A statement that forms a component of another statement is called the "body" of the enclosing statement. Each statement type given by the following syntax is discussed in this section.

Syntax

statement:

labeled-statement

compound-statement

expression-statement

selection-statement

iteration-statement

jump-statement

try-except-statement

/* Microsoft Specific */try-finally-statement /* Microsoft Specific */

Frequently the statement body is a "compound statement." A compound statement consists of other statements that can include keywords. The compound statement is delimited by braces ({ }). All other C statements end with a semicolon (;). The semicolon is a statement terminator.

The expression statement contains a C expression that can contain the arithmetic or logical operators introduced in Expressions and Assignments. The null statement is an empty statement.

Any C statement can begin with an identifying label consisting of a name and a colon. Since only the goto statement recognizes statement labels, statement labels are discussed with goto. See The goto and Labeled Statements for more information.

break Statement (C)

10/11/2017 • 1 min to read • Edit Online

The break statement terminates the execution of the nearest enclosing do, for, switch, or while statement in which it appears. Control passes to the statement that follows the terminated statement.

Syntax

jump-statement:

break;

The break statement is frequently used to terminate the processing of a particular case within a switch statement. Lack of an enclosing iterative or switch statement generates an error.

Within nested statements, the break statement terminates only the do, for, switch, or while statement that immediately encloses it. You can use a return or goto statement to transfer control elsewhere out of the nested structure.

This example illustrates the break statement:

```
#include <stdio.h>
int main() {
   char c;
   for(;;) {
      printf_s( "\nPress any key, Q to quit: " );

      // Convert to character value
      scanf_s("%c", &c);
      if (c == 'Q')
           break;
   }
} // Loop exits only when 'Q' is pressed
```

Compound Statement (C)

10/11/2017 • 1 min to read • Edit Online

A compound statement (also called a "block") typically appears as the body of another statement, such as the **if** statement. Declarations and Types describes the form and meaning of the declarations that can appear at the head of a compound statement.

Syntax

compound-statement:
{ declaration-list optstatement-listopt}
declaration-list:
declaration
declaration
statement-list:

statement-ust

statement-list statement

If there are declarations, they must come before any statements. The scope of each identifier declared at the beginning of a compound statement extends from its declaration point to the end of the block. It is visible throughout the block unless a declaration of the same identifier exists in an inner block.

Identifiers in a compound statement are presumed **auto** unless explicitly declared otherwise with **register**, **static**, or extern, except functions, which can only be extern. You can leave off the extern specifier in function declarations and the function will still be extern.

Storage is not allocated and initialization is not permitted if a variable or function is declared in a compound statement with storage class extern. The declaration refers to an external variable or function defined elsewhere.

Variables declared in a block with the **auto** or **register** keyword are reallocated and, if necessary, initialized each time the compound statement is entered. These variables are not defined after the compound statement is exited. If a variable declared inside a block has the **static** attribute, the variable is initialized when program execution begins and keeps its value throughout the program. See Storage Classes for information about **static**.

This example illustrates a compound statement:

```
if ( i > 0 )
{
    line[i] = x;
    x++;
    i--;
}
```

In this example, if i is greater than 0, all statements inside the compound statement are executed in order.

continue Statement (C)

10/11/2017 • 1 min to read • Edit Online

The continue statement passes control to the next iteration of the nearest enclosing do, for, or while statement in which it appears, bypassing any remaining statements in the do, for, or while statement body.

Syntax

```
jump-statement :
continue;
```

The next iteration of a do , for , or while statement is determined as follows:

- Within a do or a while statement, the next iteration starts by reevaluating the expression of the do or while statement.
- A continue statement in a for statement causes the loop expression of the for statement to be evaluated. Then the compiler reevaluates the conditional expression and, depending on the result, either terminates or iterates the statement body. See The for Statement for more information on the for statement and its nonterminals.

This is an example of the continue statement:

```
while ( i-- > 0 )
{
    x = f( i );
    if ( x == 1 )
        continue;
    y += x * x;
}
```

In this example, the statement body is executed while i is greater than 0. First f(i) is assigned to x; then, if x is equal to 1, the continue statement is executed. The rest of the statements in the body are ignored, and execution resumes at the top of the loop with the evaluation of the loop's test.

do-while Statement (C)

10/11/2017 • 1 min to read • Edit Online

The do-while statement lets you repeat a statement or compound statement until a specified expression becomes false.

Syntax

iteration-statement:

do statement while (expression);

The *expression* in a do-while statement is evaluated after the body of the loop is executed. Therefore, the body of the loop is always executed at least once.

The expression must have arithmetic or pointer type. Execution proceeds as follows:

- 1. The statement body is executed.
- 2. Next, *expression* is evaluated. If *expression* is false, the do-while statement terminates and control passes to the next statement in the program. If *expression* is true (nonzero), the process is repeated, beginning with step 1.

The do-while statement can also terminate when a **break**, goto , or return statement is executed within the statement body.

This is an example of the do-while statement:

```
do
{
    y = f( x );
    x--;
} while ( x > 0 );
```

In this do-while statement, the two statements y = f(x); and x--; are executed, regardless of the initial value of x. Then x > 0 is evaluated. If x is greater than 0, the statement body is executed again and x > 0 is reevaluated. The statement body is executed repeatedly as long as x remains greater than 0. Execution of the do-while statement terminates when x becomes 0 or negative. The body of the loop is executed at least once.

Expression Statement (C)

10/11/2017 • 1 min to read • Edit Online

When an expression statement is executed, the expression is evaluated according to the rules outlined in Expressions and Assignments.

Syntax

expression-statement: expression opt;

All side effects from the expression evaluation are completed before the next statement is executed. An empty expression statement is called a null statement. See The Null Statement for more information.

These examples demonstrate expression statements.

In the last statement, the function-call expression, the value of the expression, which includes any value returned by the function, is increased by 3 and then assigned to both the variables y and z.

for Statement (C)

10/11/2017 • 1 min to read • Edit Online

The **for** statement lets you repeat a statement or compound statement a specified number of times. The body of a **for** statement is executed zero or more times until an optional condition becomes false. You can use optional expressions within the **for** statement to initialize and change values during the **for** statement's execution.

Syntax

iteration-statement:

for (init-expression_{opt}; cond-expression_{opt}; loop-expression_{opt}) statement

Execution of a **for** statement proceeds as follows:

- 1. The *init-expression*, if any, is evaluated. This specifies the initialization for the loop. There is no restriction on the type of *init-expression*.
- 2. The *cond-expression*, if any, is evaluated. This expression must have arithmetic or pointer type. It is evaluated before each iteration. Three results are possible:
 - If *cond-expression* is **true** (nonzero), *statement* is executed; then *loop-expression*, if any, is evaluated. The *loop-expression* is evaluated after each iteration. There is no restriction on its type. Side effects will execute in order. The process then begins again with the evaluation of *cond-expression*.
 - If cond-expression is omitted, cond-expression is considered true, and execution proceeds exactly as
 described in the previous paragraph. A for statement without a cond-expression argument
 terminates only when a break or return statement within the statement body is executed, or when a
 goto (to a labeled statement outside the for statement body) is executed.
 - If *cond-expression* is **false** (0), execution of the **for** statement terminates and control passes to the next statement in the program.

A **for** statement also terminates when a **break**, **goto**, or **return** statement within the statement body is executed. A **continue** statement in a **for** loop causes *loop-expression* to be evaluated. When a **break** statement is executed inside a **for** loop, *loop-expression* is not evaluated or executed. This statement

for(;;)

is the customary way to produce an infinite loop which can only be exited with a break, goto, or return statement.

Code

This example illustrates the **for** statement:

```
// c_for.c
int main()
  char* line = "H e \tl\tlo World\0";
  int space = 0;
  int tab = 0;
  int i;
  int max = strlen(line);
  for (i = 0; i < max; i++ )
     if ( line[i] == ' ' )
         space++;
     if ( line[i] == '\t' )
         tab++;
  }
  printf("Number of spaces: %i\n", space);
  printf("Number of tabs: %i\n", tab);
  return 0;
}
```

Output

```
Number of spaces: 4
Number of tabs: 2
```

goto and Labeled Statements (C)

10/11/2017 • 1 min to read • Edit Online

The goto statement transfers control to a label. The given label must reside in the same function and can appear before only one statement in the same function.

Syntax

statement:
labeled-statement
jump-statement:
jump-statement:
goto identifier;
labeled-statement:

identifier: statement

A statement label is meaningful only to a goto statement; in any other context, a labeled statement is executed without regard to the label.

A *jump-statement* must reside in the same function and can appear before only one statement in the same function. The set of *identifier* names following a goto has its own name space so the names do not interfere with other identifiers. Labels cannot be redeclared. See Name Spaces for more information.

It is good programming style to use the **break**, **continue**, and return statement in preference to goto whenever possible. Since the **break** statement only exits from one level of the loop, a goto may be necessary for exiting a loop from within a deeply nested loop.

This example demonstrates the goto statement:

```
// goto.c
#include <stdio.h>
int main()
{
    int i, j;
    for ( i = 0; i < 10; i++ )
    {
        printf_s( "Outer loop executing. i = %d\n", i );
        for ( j = 0; j < 3; j++ )
        {
            printf_s( "Inner loop executing. j = %d\n", j );
            if ( i == 5 )
                 goto stop;
        }
    }
    /* This message does not print: */
    printf_s( "Loop exited. i = %d\n", i );
    stop: printf_s( "Jumped to stop. i = %d\n", i );
}</pre>
```

In this example, a goto statement transfers control to the point labeled stop when i equals 5.

if Statement (C)

10/11/2017 • 1 min to read • Edit Online

The **if** statement controls conditional branching. The body of an **if** statement is executed if the value of the expression is nonzero. The syntax for the **if** statement has two forms.

Syntax

selection-statement:

if (expression **)** statement

if (expression) statement else statement

In both forms of the **if** statement, the expressions, which can have any value except a structure, are evaluated, including all side effects.

In the first form of the syntax, if *expression* is true (nonzero), *statement* is executed. If *expression* is false, *statement* is ignored. In the second form of syntax, which uses **else**, the second *statement* is executed if *expression* is false. With both forms, control then passes from the **if** statement to the next statement in the program unless one of the statements contains a **break**, **continue**, or goto.

The following are examples of the if statement:

```
if ( i > 0 )
    y = x / i;
else
{
    x = i;
    y = f( x );
}
```

In this example, the statement y = x/i; is executed if i is greater than 0. If i is less than or equal to 0, i is assigned to x and f(x) is assigned to y. Note that the statement forming the **if** clause ends with a semicolon.

When nesting **if** statements and **else** clauses, use braces to group the statements and clauses into compound statements that clarify your intent. If no braces are present, the compiler resolves ambiguities by associating each **else** with the closest **if** that lacks an **else**.

The **else** clause is associated with the inner **if** statement in this example. If i is less than or equal to 0, no value is assigned to x.

The braces surrounding the inner **if** statement in this example make the **else** clause part of the outer **if** statement. If \vec{i} is less than or equal to 0, \vec{i} is assigned to \vec{x} .

Null Statement (C)

10/11/2017 • 1 min to read • Edit Online

A "null statement" is a statement containing only a semicolon; it can appear wherever a statement is expected. Nothing happens when a null statement is executed. The correct way to code a null statement is:

Syntax

```
;
```

Remarks

Statements such as **do**, **for**, **if**, and while require that an executable statement appear as the statement body. The null statement satisfies the syntax requirement in cases that do not need a substantive statement body.

As with any other C statement, you can include a label before a null statement. To label an item that is not a statement, such as the closing brace of a compound statement, you can label a null statement and insert it immediately before the item to get the same effect.

This example illustrates the null statement:

```
for ( i = 0; i < 10; line[i++] = 0 )
;
```

In this example, the loop expression of the **for** statement | line[i++] = 0 | initializes the first 10 elements of | line | to 0. The statement body is a null statement, since no further statements are necessary.

return Statement (C)

10/11/2017 • 2 min to read • Edit Online

The return statement terminates the execution of a function and returns control to the calling function. Execution resumes in the calling function at the point immediately following the call. A return statement can also return a value to the calling function. See Return Type for more information.

Syntax

jump-statement:

return expression opt;

The value of *expression*, if present, is returned to the calling function. If *expression* is omitted, the return value of the function is undefined. The expression, if present, is evaluated and then converted to the type returned by the function. If the function was declared with return type void, a return statement containing an expression generates a warning and the expression is not evaluated.

If no return statement appears in a function definition, control automatically returns to the calling function after the last statement of the called function is executed. In this case, the return value of the called function is undefined. If a return value is not required, declare the function to have void return type; otherwise, the default return type is int.

Many programmers use parentheses to enclose the *expression* argument of the return statement. However, C does not require the parentheses.

This example demonstrates the return statement:

```
#include <limits.h>
#include <stdio.h>
void draw( int i, long long ll );
long long sq( int s );
int main()
   long long y;
   int x = INT MAX;
    y = sq(x);
   draw(x, y);
    return x;
}
long long sq( int s )
    // Note that parentheses around the return expression
    // are allowed but not required here.
    return( s * (long long)s );
}
void draw( int i, long long ll )
{
    printf( "i = %d, 11 = %lld\n", i, 11 );
    return:
}
```

In this example, the main function calls two functions: sq and draw. The sq function returns the value of x * x to main, where the return value is assigned to y. The parentheses around the return expression in sq are evaluated as part of the expression, and are not required by the return statement. Since the return expression is evaluated before it is converted to the return type, sq forces the expression type to be the return type with a cast to prevent a possible integer overflow, which could lead to unexpected results. The draw function is declared as a void function. It prints the values of its parameters and then the empty return statement ends the function and does not return a value. An attempt to assign the return value of draw would cause a diagnostic message to be issued. The main function then returns the value of x to the operating system.

The output of the example looks like this:

```
i = 2147483647, l1 = 4611686014132420609
```

switch Statement (C)

10/11/2017 • 3 min to read • Edit Online

The switch and case statements help control complex conditional and branching operations. The statement transfers control to a statement within its body.

Syntax

}

selection-statement: **switch** (*expression*) *statement* labeled-statement: case constant-expression: statement default: statement Control passes to the statement whose case constant-expression matches the value of switch (expression). The switch statement can include any number of **case** instances, but no two case constants within the same switch statement can have the same value. Execution of the statement body begins at the selected statement and proceeds until the end of the body or until a break statement transfers control out of the body. Use of the switch statement usually looks something like this: switch (expression) declarations case constant-expression: statements executed if the expression equals the value of this constant-expression break; default: statements executed if expression does not equal any case constant-expression

You can use the break statement to end processing of a particular case within the switch statement and to branch

to the end of the switch statement. Without **break**, the program continues to the next case, executing the statements until a **break** or the end of the statement is reached. In some situations, this continuation may be desirable.

The **default** statement is executed if no **case** constant-expression is equal to the value of **switch** (expression). If the **default** statement is omitted, and no **case** match is found, none of the statements in the switch body are executed. There can be at most one **default** statement. The **default** statement need not come at the end; it can appear anywhere in the body of the switch statement. A **case** or **default** label can only appear inside a switch statement.

The type of switch expression and case constant-expression must be integral. The value of each case constant-expression must be unique within the statement body.

The **case** and **default** labels of the statement body are significant only in the initial test that determines where execution starts in the statement body. Switch statements can be nested. Any static variables are initialized before executing into any switch statements.

NOTE

Declarations can appear at the head of the compound statement forming the switch body, but initializations included in the declarations are not performed. The switch statement transfers control directly to an executable statement within the body, bypassing the lines that contain initializations.

The following examples illustrate switch statements:

```
switch( c )
{
    case 'A':
        capa++;
    case 'a':
        lettera++;
    default :
        total++;
}
```

All three statements of the switch body in this example are executed if c is equal to 'A' since a **break** statement does not appear before the following case. Execution control is transferred to the first statement (capa++;) and continues in order through the rest of the body. If c is equal to 'a', lettera and total are incremented. Only total is incremented if c is not equal to 'A' or 'a'.

```
switch( i )
{
    case -1:
        n++;
        break;
    case 0:
        z++;
        break;
    case 1:
        p++;
        break;
}
```

In this example, a **break** statement follows each statement of the switch body. The **break** statement forces an exit from the statement body after one statement is executed. If i is equal to -1, only n is incremented. The **break** following the statement n++; causes execution control to pass out of the statement body, bypassing the remaining

statements. Similarly, if i is equal to 0, only z is incremented; if i is equal to 1, only p is incremented. The final **break** statement is not strictly necessary, since control passes out of the body at the end of the compound statement, but it is included for consistency.

A single statement can carry multiple **case** labels, as the following example shows:

```
case 'a' :
  case 'b' :
  case 'c' :
  case 'd' :
  case 'e' :
  case 'f' : hexcvt(c);
```

In this example, if constant-expression equals any letter between 'a' and 'f', the hexcvt function is called.

Microsoft Specific

Microsoft C does not limit the number of case values in a switch statement. The number is limited only by the available memory. ANSI C requires at least 257 case labels be allowed in a switch statement.

The default for Microsoft C is that the Microsoft extensions are enabled. Use the /Za compiler option to disable these extensions.

try-except Statement (C)

10/11/2017 • 3 min to read • Edit Online

Microsoft Specific

The **try-except** statement is a Microsoft extension to the C language that enables applications to gain control of a program when events that normally terminate execution occur. Such events are called exceptions, and the mechanism that deals with exceptions is called structured exception handling.

Exceptions can be either hardware- or software-based. Even when applications cannot completely recover from hardware or software exceptions, structured exception handling makes it possible to display error information and trap the internal state of the application to help diagnose the problem. This is especially useful for intermittent problems that cannot be reproduced easily.

Syntax

| try-except-statement: |
|---|
| try compound-statement |
| _except (expression) compound-statement |
| The compound statement after thetry clause is the guarded section. The compound statement after theexcept clause is the exception handler. The handler specifies a set of actions to be taken if an exception is raised during execution of the guarded section. Execution proceeds as follows: |
| 1. The guarded section is executed. |
| 2. If no exception occurs during execution of the guarded section, execution continues at the statement after theexcept clause. |
| 3. If an exception occurs during execution of the guarded section or in any routine the guarded section calls, theexcept expression is evaluated and the value returned determines how the exception is handled. There are three values: |
| EXCEPTION_CONTINUE_SEARCH Exception is not recognized. Continue to search up the stack for a handler, first for containing try-except statements, then for handlers with the next highest precedence. |
| EXCEPTION_CONTINUE_EXECUTION Exception is recognized but dismissed. Continue execution at the point where the exception occurred. |
| EXCEPTION_EXECUTE_HANDLER Exception is recognized. Transfer control to the exception handler by executing theexcept compound statement, then continue execution at the point the exception occurred. |
| Because theexcept expression is evaluated as a C expression, it is limited to a single value, the conditional-expression operator, or the comma operator. If more extensive processing is required, the expression can call a routine that returns one of the three values listed above. |

NOTE

Structured exception handling works with C and C++ source files. However, it is not specifically designed for C++. You can ensure that your code is more portable by using C++ exception handling. Also, the C++ exception handling mechanism is much more flexible, in that it can handle exceptions of any type.

NOTE

For C++ programs, C++ exception handling should be used instead of structured exception handling. For more information, see Exception Handling in the C++ Language Reference.

Each routine in an application can have its own exception handler. The __except expression executes in the scope of the __try body. This means it has access to any local variables declared there.

The __leave keyword is valid within a **try-except** statement block. The effect of __leave is to jump to the end of the **try-except** block. Execution resumes after the end of the exception handler. Although a __goto _ statement can be used to accomplish the same result, a __goto _ statement causes stack unwinding. The __leave __statement is more efficient because it does not involve stack unwinding.

Exiting a **try-except** statement using the longjmp run-time function is considered abnormal termination. It is illegal to jump into a try statement, but legal to jump out of one. The exception handler is not called if a process is killed in the middle of executing a **try-except** statement.

Example

Following is an example of an exception handler and a termination handler. See The try-finally Statement for more information about termination handlers.

```
.
.
puts("hello");
__try{
    puts("in try");
    __try{
       puts("in try");
       RAISE_AN_EXCEPTION();
    }__finally{
       puts("in finally");
    }
}_except( puts("in filter"), EXCEPTION_EXECUTE_HANDLER ){
    puts("in except");
}
puts("world");
```

try-finally Statement (C)

try-finally-statement:

The try-finally statement is a Microsoft extension to the C language that enables applications to guarantee execution of cleanup code when execution of a block of code is interrupted. Cleanup consists of such tasks as deallocating memory, closing files, and releasing file handles. The try-finally statement is especially useful for routines that have several places where a check is made for an error that could cause premature return from the routine.

| try compound-statement |
|---|
| finally compound-statement |
| The compound statement after thetry clause is the guarded section. The compound statement after thefinally clause is the termination handler. The handler specifies a set of actions that execute when the guarded section is exited, whether the guarded section is exited by an exception (abnormal termination) or by standard fall through (normal termination). |
| Control reaches atry statement by simple sequential execution (fall through). When control enters thetry statement, its associated handler becomes active. Execution proceeds as follows: |
| 1. The guarded section is executed. |
| 2. The termination handler is invoked. |
| 3. When the termination handler completes, execution continues after thefinally statement. Regardless of how the guarded section ends (for example, via a goto statement out of the guarded body or via a return statement), the termination handler is executed before the flow of control moves out of the guarded section. |
| Theleave keyword is valid within a try-finally statement block. The effect ofleave is to jump to the end of the try-finally block. The termination handler is immediately executed. Although a goto statement can be used to accomplish the same result, a goto statement causes stack unwinding. Theleave statement is more efficient because it does not involve stack unwinding. |
| Exiting a try-finally statement using a return statement or the longjmp run-time function is considered abnormal termination. It is illegal to jump into a try statement, but legal to jump out of one. All statements that are active between the point of departure and the destination must be run. This is called a "local unwind." |
| The termination handler is not called if a process is killed while executing a try-finally statement. |

NOTE

Structured exception handling works with C and C++ source files. However, it is not specifically designed for C++. You can ensure that your code is more portable by using C++ exception handling. Also, the C++ exception handling mechanism is much more flexible, in that it can handle exceptions of any type.

NOTE

while Statement (C)

10/11/2017 • 1 min to read • Edit Online

The while statement lets you repeat a statement until a specified expression becomes false.

Syntax

iteration-statement:

while (expression) statement

The expression must have arithmetic or pointer type. Execution proceeds as follows:

- 1. The expression is evaluated.
- 2. If *expression* is initially false, the body of the while statement is never executed, and control passes from the while statement to the next statement in the program.

If *expression* is true (nonzero), the body of the statement is executed and the process is repeated beginning at step 1.

The while statement can also terminate when a **break**, goto, or return within the statement body is executed. Use the **continue** statement to terminate an iteration without exiting the while loop. The **continue** statement passes control to the next iteration of the while statement.

This is an example of the while statement:

```
while ( i >= 0 )
{
    string1[i] = string2[i];
    i--;
}
```

This example copies characters from string2 to string1. If i is greater than or equal to 0, string2[i] is assigned to string1[i] and i is decremented. When i reaches or falls below 0, execution of the while statement terminates.

Overview of Functions

10/11/2017 • 1 min to read • Edit Online

Functions must have a definition and should have a declaration, although a definition can serve as a declaration if the declaration appears before the function is called. The function definition includes the function body — the code that executes when the function is called.

A function declaration establishes the name, return type, and attributes of a function that is defined elsewhere in the program. A function declaration must precede the call to the function. This is why the header files containing the declarations for the run-time functions are included in your code before a call to a run-time function. If the declaration has information about the types and number of parameters, the declaration is a prototype. See Function Prototypes for more information.

The compiler uses the prototype to compare the types of arguments in subsequent calls to the function with the function's parameters and to convert the types of the arguments to the types of the parameters whenever necessary.

A function call passes execution control from the calling function to the called function. The arguments, if any, are passed by value to the called function. Execution of a return statement in the called function returns control and possibly a value to the calling function.

Obsolete Forms of Function Declarations and Definitions

10/11/2017 • 1 min to read • Edit Online

The old-style function declarations and definitions use slightly different rules for declaring parameters than the syntax recommended by the ANSI C standard. First, the old-style declarations don't have a parameter list. Second, in the function definition, the parameters are listed, but their types are not declared in the parameter list. The type declarations precede the compound statement constituting the function body. The old-style syntax is obsolete and should not be used in new code. Code using the old-style syntax is still supported, however. This example illustrates the obsolete forms of declarations and definitions:

Functions returning an integer or pointer with the same size as an int are not required to have a declaration although the declaration is recommended.

To comply with the ANSI C standard, old-style function declarations using an ellipsis now generate an error when compiling with the /Za option and a level 4 warning when compiling with /Ze. For example:

You should rewrite this declaration as a prototype:

```
void funct1( int a, ... )
{
}
```

Old-style function declarations also generate warnings if you subsequently declare or define the same function with either an ellipsis or a parameter with a type that is not the same as its promoted type.

The next section, C Function Definitions, shows the syntax for function definitions, including the old-style syntax. The nonterminal for the list of parameters in the old-style syntax is *identifier-list*.

A function definition specifies the name of the function, the types and number of parameters it expects to receive, and its return type. A function definition also includes a function body with the declarations of its local variables, and the statements that determine what the function does.

Syntax

```
translation-unit:
external-declaration
translation-unit external-declaration
external-declaration: /* Allowed only at external (file) scope */
function-definition
declaration
function-definition: /* Declarator here is the function declarator */
declaration-specifiers optattribute-seq optdeclarator declaration-list optcompound-statement
/* attribute-seq is Microsoft Specific */
Prototype parameters are:
declaration-specifiers:
storage-class-specifier declaration-specifiers opt
type-specifier declaration-specifiers opt
type-qualifier declaration-specifiers opt
declaration-list:

declaration-list declaration
declarator:
pointer optdirect-declarator
direct-declarator: /* A function declarator */
direct-declarator ( parameter-type-list ) /* New-style declarator */
direct-declarator (identifier-list opt) /* Obsolete-style declarator */
The parameter list in a definition uses this syntax:
parameter-type-list: /* The parameter list */
parameter-list
parameter-list, ...
parameter-list:
parameter-declaration
```

parameter-list, parameter-declaration

parameter-declaration: declaration-specifiers declarator

declaration-specifiers abstract declarator opt

The parameter list in an old-style function definition uses this syntax:

identifier-list: /* Used in obsolete-style function definitions and declarations */ *identifier*

identifier-list, identifier

The syntax for the function body is:

compound-statement: /* The function body */
{ declaration -list optstatement-list opt}

The only storage-class specifiers that can modify a function declaration are extern and **static**. The extern specifier signifies that the function can be referenced from other files; that is, the function name is exported to the linker. The **static** specifier signifies that the function cannot be referenced from other files; that is, the name is not exported by the linker. If no storage class appears in a function definition, extern is assumed. In any case, the function is always visible from the definition point to the end of the file.

The optional *declaration-specifiers* and mandatory declarator together specify the function's return type and name. The declarator is a combination of the identifier that names the function and the parentheses following the function name. The optional *attribute-seq* nonterminal is a Microsoft-specific feature defined in Function Attributes.

The *direct-declarator* (in the declarator syntax) specifies the name of the function being defined and the identifiers of its parameters. If the *direct-declarator* includes a *parameter-type-list*, the list specifies the types of all the parameters. Such a declarator also serves as a function prototype for later calls to the function.

A declaration in the declaration-list in function definitions cannot contain a storage-class-specifier other than **register**. The type-specifier in the declaration-specifiers syntax can be omitted only if the **register** storage class is specified for a value of int type.

The *compound-statement* is the function body containing local variable declarations, references to externally declared items, and statements.

The sections Function Attributes, Storage Class, Return Type, Parameters, and Function Body describe the components of the function definition in detail.

Inline Functions

10/21/2017 • 1 min to read • Edit Online

Microsoft Specific

The __inline keyword tells the compiler to substitute the code within the function definition for every instance of a function call. However, substitution occurs only at the compiler's discretion. For example, the compiler does not inline a function if its address is taken or if it is too large to inline.

For a function to be considered as a candidate for inlining, it must use the new-style function definition.

Use this form to specify an inline function:

__inline type_{opt} function-definition

The use of inline functions generates faster code and can sometimes generate smaller code than the equivalent function call generates for the following reasons:

- It saves the time required to execute function calls.
- Small inline functions, perhaps three lines or less, create less code than the equivalent function call because the compiler doesn't generate code to handle arguments and a return value.
- Functions generated inline are subject to code optimizations not available to normal functions because the compiler does not perform interprocedural optimizations.

Functions using __inline should not be confused with inline assembler code. See Inline Assembler for more information.

Inline Assembler (C)

10/11/2017 • 1 min to read • Edit Online

Microsoft Specific

The inline assembler lets you embed assembly-language instructions directly in your C source programs without extra assembly and link steps. The inline assembler is built into the compiler — you don't need a separate assembler such as the Microsoft Macro Assembler (MASM).

Because the inline assembler doesn't require separate assembly and link steps, it is more convenient than a separate assembler. Inline assembly code can use any C variable or function name that is in scope, so it is easy to integrate it with your program's C code. And because the assembly code can be mixed with C statements, it can do tasks that are cumbersome or impossible in C alone.

The __asm keyword invokes the inline assembler and can appear wherever a C statement is legal. It cannot appear by itself. It must be followed by an assembly instruction, a group of instructions enclosed in braces, or, at the very least, an empty pair of braces. The term "__asm block" here refers to any instruction or group of instructions, whether or not in braces.

The code below is a simple __asm block enclosed in braces. (The code is a custom function prolog sequence.)

```
__asm
{
    push ebp
    mov ebp, esp
    sub esp, __LOCAL_SIZE
}
```

Alternatively, you can put __asm in front of each assembly instruction:

```
__asm push ebp
__asm mov ebp, esp
__asm sub esp, __LOCAL_SIZE
```

Since the _asm keyword is a statement separator, you can also put assembly instructions on the same line:

```
__asm push ebp __asm mov ebp, esp __asm sub esp, __LOCAL_SIZE
```

DLL Import and Export Functions

Microsoft Specific

The most complete and up-to-date information on this topic can be found in dllexport, dllimport.

The **dllimport** and dllexport storage-class modifiers are Microsoft-specific extensions to the C language. These modifiers explicitly define the DLL's interface to its client (the executable file or another DLL). Declaring functions as dllexport eliminates the need for a module-definition (.DEF) file. You can also use the **dllimport** and dllexport modifiers with data and objects.

The **dllimport** and dllexport storage-class modifiers must be used with the extended attribute syntax keyword, declspec, as shown in this example:

```
#define DllImport __declspec( dllimport )
#define DllExport __declspec( dllexport )

DllExport void func();
DllExport int i = 10;
DllExport int j;
DllExport int n;
```

The DLL interface refers to all items (functions and data) that are known to be exported by some program in the system; that is, all items that are declared as **dllimport** or dllexport. All declarations included in the DLL interface must specify either the **dllimport** or dllexport attribute. However, the definition can specify only the dllexport attribute. For example, the following function definition generates a compiler error:

This code also generates an error:

```
#define DllImport __declspec( dllimport )
#define DllExport __declspec( dllexport )

DllImport int i = 10;  /* Error; this is a definition. */
```

However, this is correct syntax:

```
#define DllImport __declspec( dllimport )
#define DllExport __declspec( dllexport )

DllExport int i = 10;  /* Okay: this is an export definition. */
```

The use of dllexport implies a definition, while **dllimport** implies a declaration. You must use the extern keyword with dllexport to force a declaration; otherwise, a definition is implied.

```
#define DllImport __declspec( dllimport )
#define DllExport __declspec( dllexport )

extern DllImport int k; /* These are correct and imply */
Dllimport int j; /* a declaration. */
```

Defining Inline C Functions with dllexport and dllimport

10/11/2017 • 1 min to read • Edit Online

Microsoft Specific

You can define as inline a function with the dllexport attribute. In this case, the function is always instantiated and exported, whether or not any module in the program references the function. The function is presumed to be imported by another program.

You can also define as inline a function declared with the **dllimport** attribute. In this case, the function can be expanded (subject to the /Ob (inline) compiler option specification) but never instantiated. In particular, if the address of an inline imported function is taken, the address of the function residing in the DLL is returned. This behavior is the same as taking the address of a non-inline imported function.

Static local data and strings in inline functions maintain the same identities between the DLL and client as they would in a single program (that is, an executable file without a DLL interface).

Exercise care when providing imported inline functions. For example, if you update the DLL, don't assume that the client will use the changed version of the DLL. To ensure that you are loading the proper version of the DLL, rebuild the DLL's client as well.

Rules and Limitations for dllimport/dllexport

10/11/2017 • 2 min to read • Edit Online

Microsoft Specific

- If you declare a function without the **dllimport** or dllexport attribute, the function is not considered part of the DLL interface. Therefore, the definition of the function must be present in that module or in another module of the same program. To make the function part of the DLL interface, you must declare the definition of the function in the other module as dllexport. Otherwise, a linker error is generated when the client is built.
- If a single module in your program contains **dllimport** and dllexport declarations for the same function, the dllexport attribute takes precedence over the **dllimport** attribute. However, a compiler warning is generated. For example:

• You cannot initialize a static data pointer with the address of a data object declared with the **dllimport** attribute. For example, the following code generates errors:

• Initializing a static function pointer with the address of a function declared with **dllimport** sets the pointer to the address of the DLL import thunk (a code stub that transfers control to the function) rather than the address of the function. This assignment does not generate an error message:

```
#define DllImport    __declspec( dllimport )
#define DllExport    __declspec( dllexport )

DllImport void func1( void
.
.
.
.
static void ( *pf )( void ) = &func1; /* No Error */

void func2()
{
    static void ( *pf )( void ) = &func1; /* No Error */
}
```

• Because a program that includes the dllexport attribute in the declaration of an object must provide the definition for that object, you can initialize a global or local static function pointer with the address of a dllexport data object. For example:

Naked Functions

10/11/2017 • 1 min to read • Edit Online

Microsoft Specific

The naked storage-class attribute is a Microsoft-specific extension to the C language. For functions declared with the naked storage-class attribute, the compiler generates code without prolog and epilog code. You can use this feature to write your own prolog/epilog code sequences using inline assembler code. Naked functions are particularly useful in writing virtual device drivers.

Because the naked attribute is only relevant to the definition of a function and is not a type modifier, naked functions use the extended attribute syntax, described in Extended Storage-Class Attributes.

The following example defines a function with the naked attribute:

```
__declspec( naked ) int func( formal_parameters )
{
    /* Function body */
}
```

Or, alternatively:

```
#define Naked __declspec( naked )

Naked int func( formal_parameters )
{
    /* Function body */
}
```

The naked attribute affects only the nature of the compiler's code generation for the function's prolog and epilog sequences. It does not affect the code that is generated for calling such functions. Thus, the naked attribute is not considered part of the function's type, and function pointers cannot have the naked attribute. Furthermore, the naked attribute cannot be applied to a data definition. For example, the following code generates errors:

The naked attribute is relevant only to the definition of the function and cannot be specified in the function's prototype. The following declaration generates a compiler error:

```
__declspec( naked ) int func();    /* Error--naked attribute not */
    /* permitted on function declarations. */ \
```

Considerations When Writing Prolog/Epilog Code

10/11/2017 • 1 min to read • Edit Online

Microsoft Specific

Before writing your own prolog and epilog code sequences, it is important to understand how the stack frame is laid out. It is also useful to know how to use the **LOCAL SIZE** predefined constant.

C Stack Frame Layout

This example shows the standard prolog code that might appear in a 32-bit function:

```
push ebp ; Save ebp
mov ebp, esp ; Set stack frame pointer
sub esp, localbytes ; Allocate space for locals
push <registers> ; Save registers
```

The localbytes variable represents the number of bytes needed on the stack for local variables, and the registers variable is a placeholder that represents the list of registers to be saved on the stack. After pushing the registers, you can place any other appropriate data on the stack. The following is the corresponding epilog code:

```
pop <registers> ; Restore registers
mov esp, ebp ; Restore stack pointer
pop ebp ; Restore ebp
ret ; Return from function
```

The stack always grows down (from high to low memory addresses). The base pointer (ebp) points to the pushed value of ebp. The local variables area begins at ebp-2. To access local variables, calculate an offset from ebp by subtracting the appropriate value from ebp.

The _LOCAL_SIZE Constant

The compiler provides a constant, __LOCAL_SIZE, for use in the inline assembler block of function prolog code. This constant is used to allocate space for local variables on the stack frame in custom prolog code.

The compiler determines the value of __LOCAL_SIZE. The value is the total number of bytes of all user-defined local variables and compiler-generated temporary variables. __LOCAL_SIZE can be used only as an immediate operand; it cannot be used in an expression. You must not change or redefine the value of this constant. For example:

```
mov eax, __LOCAL_SIZE ;Immediate operand--Okay
mov eax, [ebp - __LOCAL_SIZE] ;Error
```

The following example of a naked function containing custom prolog and epilog sequences uses **__LOCAL_SIZE** in the prolog sequence:

```
__declspec ( naked ) func()
 int i;
 int j;
 {
   push ebp
   mov ebp, esp
       esp, __LOCAL_SIZE
   sub
   }
 /* Function body */
        /* epilog */
  __asm
   {
       esp, ebp
   mov
   pop
        ebp
   ret
}
```

END Microsoft Specific

Storage Class

10/11/2017 • 1 min to read • Edit Online

The storage-class specifier in a function definition gives the function either extern or **static** storage class.

Syntax

function-definition:

declaration-specifiers optattribute-seq optdeclarator declaration-list optcompound-statement

/* attribute-seq is Microsoft Specific */

declaration-specifiers:

storage-class-specifier declaration-specifiers opt

type-specifier declaration-specifiers opt

type-qualifier declaration-specifiers opt

storage-class-specifier: /* For function definitions */

extern

static

If a function definition does not include a *storage-class-specifier*, the storage class defaults to extern. You can explicitly declare a function as extern, but it is not required.

If the declaration of a function contains the *storage-class-specifier* extern, the identifier has the same linkage as any visible declaration of the identifier with file scope. If there is no visible declaration with file scope, the identifier has external linkage. If an identifier has file scope and no *storage-class-specifier*, the identifier has external linkage. External linkage means that each instance of the identifier denotes the same object or function. See Lifetime, Scope, Visibility, and Linkage for more information about linkage and file scope.

Block-scope function declarations with a storage-class specifier other than extern generate errors.

A function with **static** storage class is visible only in the source file in which it is defined. All other functions, whether they are given extern storage class explicitly or implicitly, are visible throughout all source files in the program. If **static** storage class is desired, it must be declared on the first occurrence of a declaration (if any) of the function, and on the definition of the function.

Microsoft Specific

When the Microsoft extensions are enabled, a function originally declared without a storage class (or with extern storage class) is given **static** storage class if the function definition is in the same source file and if the definition explicitly specifies **static** storage class.

When compiling with the /Ze compiler option, functions declared within a block using the extern keyword have global visibility. This is not true when compiling with /Za. This feature should not be relied upon if portability of source code is a consideration.

Return Type

10/11/2017 • 1 min to read • Edit Online

The return type of a function establishes the size and type of the value returned by the function and corresponds to the type-specifier in the syntax below:

Syntax

| function-definition: declaration-specifiers optattribute-seq optdeclarator declaration-list optcompound-statement |
|--|
| /* attribute-seq is Microsoft Specific */ |
| declaration-specifiers: storage-class-specifier declaration-specifiers opt |
| type-specifier declaration-specifiers opt |
| type-qualifier declaration-specifiers opt |
| type-specifier: void |
| char |
| short |
| int |
| long |
| float |
| double |
| signed |
| unsigned |
| struct-or-union-specifier |
| enum-specifier |
| typedef-name |
| The <i>type-specifier</i> can specify any fundamental, structure, or union type. If you do not include <i>type-specifier</i> , the return type int is assumed. |
| |

The return type given in the function definition must match the return type in declarations of the function elsewhere in the program. A function returns a value when a return statement containing an expression is executed. The expression is evaluated, converted to the return value type if necessary, and returned to the point at which the function was called. If a function is declared with return type void, a return statement containing an expression generates a warning and the expression is not evaluated.

The following examples illustrate function return values.

```
typedef struct
{
    char name[20];
    int id;
    long class;
} STUDENT;

/* Return type is STUDENT: */

STUDENT sortstu( STUDENT a, STUDENT b )
{
    return ( (a.id < b.id) ? a : b );
}</pre>
```

This example defines the STUDENT type with a typedef declaration and defines the function sortstu to have STUDENT return type. The function selects and returns one of its two structure arguments. In subsequent calls to the function, the compiler checks to make sure the argument types are STUDENT.

NOTE

Efficiency would be enhanced by passing pointers to the structure, rather than the entire structure.

```
char *smallstr( char s1[], char s2[] )
{
   int i;

   i = 0;
   while ( s1[i] != '\0' && s2[i] != '\0' )
        i++;
   if ( s1[i] == '\0' )
        return ( s1 );
   else
        return ( s2 );
}
```

This example defines a function returning a pointer to an array of characters. The function takes two character arrays (strings) as arguments and returns a pointer to the shorter of the two strings. A pointer to an array points to the first of the array elements and has its type; thus, the return type of the function is a pointer to type char.

You need not declare functions with int return type before you call them, although prototypes are recommended so that correct type checking for arguments and return values is enabled.

Parameters

10/11/2017 • 2 min to read • Edit Online

Arguments are names of values passed to a function by a function call. Parameters are the values the function expects to receive. In a function prototype, the parentheses following the function name contain a complete list of the function's parameters and their types. Parameter declarations specify the types, sizes, and identifiers of values stored in the parameters.

Syntax

```
function-definition:
declaration-specifiers optattribute-seq optdeclarator declaration-list optcompound-statement
/* attribute-seq is Microsoft Specific */
declarator:
pointer optdirect-declarator
direct-declarator:/* A function declarator */
direct-declarator ( parameter-type-list ) /* New-style declarator */
parameter-type-list: /* A parameter list */
parameter-list
parameter-list ,...
parameter-list:
parameter-declaration
parameter-list, parameter-declaration
parameter-declaration:
declaration-specifiers declarator
declaration-specifiers abstract-declarator opt
```

The *parameter-type-list* is a sequence of parameter declarations separated by commas. The form of each parameter in a parameter list looks like this:

```
[register] type-specifier [declarator]
```

Function parameters declared with the **auto** attribute generate errors. The identifiers of the parameters are used in the function body to refer to the values passed to the function. You can name the parameters in a prototype, but the names go out of scope at the end of the declaration. Therefore parameter names can be assigned the same way or differently in the function definition. These identifiers cannot be redefined in the outermost block of the function body, but they can be redefined in inner, nested blocks as though the parameter list were an enclosing block.

Each identifier in parameter-type-list must be preceded by its appropriate type specifier, as shown in this example:

```
void new( double x, double y, double z )
{
    /* Function body here */
}
```

If at least one parameter occurs in the parameter list, the list can end with a comma followed by three periods (, ...). This construction, called the "ellipsis notation," indicates a variable number of arguments to the function. (See Calls with a Variable Number of Arguments for more information.) However, a call to the function must have at least as many arguments as there are parameters before the last comma.

If no arguments are to be passed to the function, the list of parameters is replaced by the keyword void. This use of void is distinct from its use as a type specifier.

The order and type of parameters, including any use of the ellipsis notation, must be the same in all the function declarations (if any) and in the function definition. The types of the arguments after usual arithmetic conversions must be assignment-compatible with the types of the corresponding parameters. (See Usual Arithmetic Conversions for information on arithmetic conversions.) Arguments following the ellipsis are not checked. A parameter can have any fundamental, structure, union, pointer, or array type.

The compiler performs the usual arithmetic conversions independently on each parameter and on each argument, if necessary. After conversion, no parameter is shorter than an <u>int</u>, and no parameter has **float** type unless the parameter type is explicitly specified as **float** in the prototype. This means, for example, that declaring a parameter as a <u>char</u> has the same effect as declaring it as an <u>int</u>.

Function Body

10/11/2017 • 1 min to read • Edit Online

A "function body" is a compound statement containing the statements that specify what the function does.

Syntax

function-definition:

declaration-specifiers optattribute-seq optdeclarator declaration-list optcompound-statement

/* attribute-seq is Microsoft Specific */

compound-statement: /* The function body */
{ declaration-list optstatement-list opt}

Variables declared in a function body, "local variables," have **auto** storage class unless otherwise specified. When the function is called, storage is created for the local variables and local initializations are performed. Execution control passes to the first statement in *compound-statement* and continues until a return statement is executed or the end of the function body is encountered. Control then returns to the point at which the function was called.

A return statement containing an expression must be executed if the function is to return a value. The return value of a function is undefined if no return statement is executed or if the return statement does not include an expression.

Function Prototypes

10/11/2017 • 3 min to read • Edit Online

A function declaration precedes the function definition and specifies the name, return type, storage class, and other attributes of a function. To be a prototype, the function declaration must also establish types and identifiers for the function's arguments.

Syntax

```
declaration:
declaration-specifiers attribute-seq optinit-declarator-list opt;
/* attribute-seq opt is Microsoft Specific */
declaration-specifiers:
storage-class-specifier declaration-specifiers opt
type-specifier declaration-specifiers opt
type-qualifier declaration-specifiers opt
init-declarator-list:
init-declarator
init-declarator-list, init-declarator
init-declarator:
declarator
declarator = initializer
declarator:
pointer optdirect-declarator
direct-declarator: /* A function declarator */
direct-declarator ( parameter-type-list ) /* New-style declarator */
direct-declarator (identifier-list opt) /* Obsolete-style declarator */
```

The prototype has the same form as the function definition, except that it is terminated by a semicolon immediately following the closing parenthesis and therefore has no body. In either case, the return type must agree with the return type specified in the function definition.

Function prototypes have the following important uses:

- They establish the return type for functions that return types other than int. Although functions that return values do not require prototypes, prototypes are recommended.
- Without complete prototypes, standard conversions are made, but no attempt is made to check the type or number of arguments with the number of parameters.
- Prototypes are used to initialize pointers to functions before those functions are defined.
- The parameter list is used for checking the correspondence of arguments in the function call with the parameters in the function definition.

The converted type of each parameter determines the interpretation of the arguments that the function call places on the stack. A type mismatch between an argument and a parameter may cause the arguments on the stack to be misinterpreted. For example, on a 16-bit computer, if a 16-bit pointer is passed as an argument, then declared as a **long** parameter, the first 32 bits on the stack are interpreted as a **long** parameter. This error creates problems not only with the **long** parameter, but with any parameters that follow it. You can detect errors of this kind by declaring complete function prototypes for all functions.

A prototype establishes the attributes of a function so that calls to the function that precede its definition (or occur in other source files) can be checked for argument-type and return-type mismatches. For example, if you specify the **static** storage-class specifier in a prototype, you must also specify the **static** storage class in the function definition.

Complete parameter declarations (int a) can be mixed with abstract declarators (int) in the same declaration. For example, the following declaration is legal:

```
int add( int a, int );
```

The prototype can include both the type of, and an identifier for, each expression that is passed as an argument. However, such identifiers have scope only until the end of the declaration. The prototype can also reflect the fact that the number of arguments is variable, or that no arguments are passed. Without such a list, mismatches may not be revealed, so the compiler cannot generate diagnostic messages concerning them. See Arguments for more information on type checking.

Prototype scope in the Microsoft C compiler is now ANSI-compliant when compiling with the /Za compiler option. This means that if you declare a struct or **union** tag within a prototype, the tag is entered at that scope rather than at global scope. For example, when compiling with /Za for ANSI compliance, you can never call this function without getting a type mismatch error:

```
void func1( struct S * );
```

To correct your code, define or declare the struct or **union** at global scope before the function prototype:

```
struct S;
void func1( struct S * );
```

Under /Ze, the tag is still entered at global scope.

Function Calls

10/11/2017 • 2 min to read • Edit Online

A function call is an expression that passes control and arguments (if any) to a function and has the form:

expression (expression-listopt)

where *expression* is a function name or evaluates to a function address and *expression-list* is a list of expressions (separated by commas). The values of these latter expressions are the arguments passed to the function. If the function does not return a value, then you declare it to be a function that returns void.

If a declaration exists before the function call, but no information is given concerning the parameters, any undeclared arguments simply undergo the usual arithmetic conversions.

NOTE

The expressions in the function argument list can be evaluated in any order, so arguments whose values may be changed by side effects from another argument have undefined values. The sequence point defined by the function-call operator guarantees only that all side effects in the argument list are evaluated before control passes to the called function. (Note that the order in which arguments are pushed on the stack is a separate matter.) See Sequence Points for more information.

The only requirement in any function call is that the expression before the parentheses must evaluate to a function address. This means that a function can be called through any function-pointer expression.

Example

This example illustrates function calls called from a switch statement:

```
int main()
{
    /* Function prototypes */
    long lift( int ), step( int ), drop( int );
    void work( int number, long (*function)(int i) );
    int select, count;
    select = 1;
    switch( select )
        case 1: work( count, lift );
                break:
        case 2: work( count, step );
               break;
        case 3: work( count, drop );
                /* Fall through to next case */
        default:
                break;
    }
}
/* Function definition */
void work( int number, long (*function)(int i) )
   int i;
   long j;
    for (i = j = 0; i < number; i++)
            j += ( *function )( i );
}
```

In this example, the function call in main,

```
work( count, lift );
```

passes an integer variable, count, and the address of the function lift to the function work. Note that the function address is passed simply by giving the function identifier, since a function identifier evaluates to a pointer expression. To use a function identifier in this way, the function must be declared or defined before the identifier is used; otherwise, the identifier is not recognized. In this case, a prototype for work is given at the beginning of the main function.

The parameter function in work is declared to be a pointer to a function taking one int argument and returning a **long** value. The parentheses around the parameter name are required; without them, the declaration would specify a function returning a pointer to a **long** value.

The function work calls the selected function from inside the **for** loop by using the following function call:

```
( *function )( i );
```

One argument, i, is passed to the called function.

Functions

Arguments

10/11/2017 • 3 min to read • Edit Online

The arguments in a function call have this form:

```
expression
(
expression-list <SUB>opt</SUB> ) /* Function call */
```

In a function call, *expression-list* is a list of expressions (separated by commas). The values of these latter expressions are the arguments passed to the function. If the function takes no arguments, *expression-list* should contain the keyword void.

An argument can be any value with fundamental, structure, union, or pointer type. All arguments are passed by value. This means a copy of the argument is assigned to the corresponding parameter. The function does not know the actual memory location of the argument passed. The function uses this copy without affecting the variable from which it was originally derived.

Although you cannot pass arrays or functions as arguments, you can pass pointers to these items. Pointers provide a way for a function to access a value by reference. Since a pointer to a variable holds the address of the variable, the function can use this address to access the value of the variable. Pointer arguments allow a function to access arrays and functions, even though arrays and functions cannot be passed as arguments.

The order in which arguments are evaluated can vary under different compilers and different optimization levels. However, the arguments and any side effects are completely evaluated before the function is entered. See Side Effects for information on side effects.

The *expression-list* in a function call is evaluated and the usual arithmetic conversions are performed on each argument in the function call. If a prototype is available, the resulting argument type is compared to the prototype's corresponding parameter. If they do not match, either a conversion is performed, or a diagnostic message is issued. The parameters also undergo the usual arithmetic conversions.

The number of expressions in *expression-list* must match the number of parameters, unless the function's prototype or definition explicitly specifies a variable number of arguments. In this case, the compiler checks as many arguments as there are type names in the list of parameters and converts them, if necessary, as described above. See Calls with a Variable Number of Arguments for more information.

If the prototype's parameter list contains only the keyword void, the compiler expects zero arguments in the function call and zero parameters in the definition. A diagnostic message is issued if it finds any arguments.

Example

This example uses pointers as arguments:

```
int main()
{
    /* Function prototype */
    void swap( int *num1, int *num2 );
    int x, y;
    .
    .
    .
    swap( &x, &y ); /* Function call */
}

/* Function definition */

void swap( int *num1, int *num2 )
{
    int t;

    t = *num1;
    *num1 = *num2;
    *num2 = t;
}
```

In this example, the swap function is declared in main to have two arguments, represented respectively by identifiers num1 and num2, both of which are pointers to int values. The parameters num1 and num2 in the prototype-style definition are also declared as pointers to int type values.

In the function call

```
swap( &x, &y )
```

the address of x is stored in num1 and the address of y is stored in num2. Now two names, or "aliases," exist for the same location. References to *num1 and *num2 in swap are effectively references to x and y in x are effectively references to x and y in x and y in x are effectively references to x and y in x and y in x are effectively references to x are effectively references to x and y in x are effectively references to x are effectively references to x and y in x are effectively references to x and y in x are effectively references to x and y in x are effectively references to x and y in

The compiler performs type checking on the arguments to swap because the prototype of swap includes argument types for each parameter. The identifiers within the parentheses of the prototype and definition can be the same or different. What is important is that the types of the arguments match those of the parameter lists in both the prototype and the definition.

Calls with a Variable Number of Arguments

10/11/2017 • 1 min to read • Edit Online

A partial parameter list can be terminated by the ellipsis notation, a comma followed by three periods (, ...), to indicate that there may be more arguments passed to the function, but no more information is given about them. Type checking is not performed on such arguments. At least one parameter must precede the ellipsis notation and the ellipsis notation must be the last token in the parameter list. Without the ellipsis notation, the behavior of a function is undefined if it receives parameters in addition to those declared in the parameter list.

To call a function with a variable number of arguments, simply specify any number of arguments in the function call. An example is the printf function from the C run-time library. The function call must include one argument for each type name declared in the parameter list or the list of argument types.

All the arguments specified in the function call are placed on the stack unless the __fastcall calling convention is specified. The number of parameters declared for the function determines how many of the arguments are taken from the stack and assigned to the parameters. You are responsible for retrieving any additional arguments from the stack and for determining how many arguments are present. The STDARG.H file contains ANSI-style macros for accessing arguments of functions which take a variable number of arguments. Also, the XENIX-style macros in VARARGS.H are still supported.

This sample declaration is for a function that calls a variable number of arguments:

int average(int first, ...);

Recursive Functions

10/11/2017 • 1 min to read • Edit Online

Any function in a C program can be called recursively; that is, it can call itself. The number of recursive calls is limited to the size of the stack. See the /STACK (Stack Allocations) (/STACK) linker option for information about linker options that set stack size. Each time the function is called, new storage is allocated for the parameters and for the **auto** and **register** variables so that their values in previous, unfinished calls are not overwritten. Parameters are only directly accessible to the instance of the function in which they are created. Previous parameters are not directly accessible to ensuing instances of the function.

Note that variables declared with **static** storage do not require new storage with each recursive call. Their storage exists for the lifetime of the program. Each reference to such a variable accesses the same storage area.

Example

This example illustrates recursive calls:

Definitions and Conventions

Terminals are endpoints in a syntax definition. No other resolution is possible. Terminals include the set of reserved words and user-defined identifiers.

Nonterminals are placeholders in the syntax and are defined elsewhere in this syntax summary. Definitions can be recursive.

An optional component is indicated by the subscripted opt. For example,

```
{
expression <SUB>opt</SUB> }
```

indicates an optional expression enclosed in braces.

The syntax conventions use different font attributes for different components of the syntax. The symbols and fonts are as follows:

| ATTRIBUTE | DESCRIPTION |
|------------------|--|
| nonterminal | Italic type indicates nonterminals. |
| const | Terminals in bold type are literal reserved words and symbols that must be entered as shown. Characters in this context are always case sensitive. |
| opt | Nonterminals followed by opt are always optional. |
| default typeface | Characters in the set described or listed in this typeface can be used as terminals in C statements. |

A colon (:) following a nonterminal introduces its definition. Alternative definitions are listed on separate lines, except when prefaced with the words "one of."

Implementation-Defined Behavior

ANSI X3.159-1989, American National Standard for Information Systems - Programming Language - C, contains a section called "Portability Issues." The ANSI section lists areas of the C language that ANSI leaves open to each particular implementation. This section describes how Microsoft C handles these implementation-defined areas of the C language.

This section follows the same order as the ANSI section. Each item covered includes references to the ANSI that explains the implementation-defined behavior.

NOTE

This section describes the U.S. English-language version of the C compiler only. Implementations of Microsoft C for other languages may differ slightly.

ANSI 2.1.1.3 How a diagnostic is identified

Microsoft C produces error messages in the form:

filename(line-number) : diagnostic Cnumbermessage

where *filename* is the name of the source file in which the error was encountered; *line-number* is the line number at which the compiler detected the error; diagnostic is either "error" or "warning"; number is a unique four-digit number (preceded by a **C**, as noted in the syntax) that identifies the error or warning; message is an explanatory message.

Arguments to main

10/11/2017 • 1 min to read • Edit Online

ANSI 2.1.2.2.1 The semantics of the arguments to main

In Microsoft C, the function called at program startup is called **main**. There is no prototype declared for **main**, and it can be defined with zero, two, or three parameters:

```
int main( void )
int main( int argc, char *argv[] )
int main( int argc, char *argv[], char *envp[] )
```

The third line above, where **main** accepts three parameters, is a Microsoft extension to the ANSI C standard. The third parameter, **envp**, is an array of pointers to environment variables. The **envp** array is terminated by a null pointer. See The main Function and Program Execution for more information about **main** and **envp**.

The variable argc never holds a negative value.

The array of strings ends with argv[argc], which contains a null pointer.

All elements of the argv array are pointers to strings.

A program invoked with no command-line arguments will receive a value of one for **argc**, as the name of the executable file is placed in **argv[0]**. (In MS-DOS versions prior to 3.0, the executable-file name is not available. The letter "C" is placed in **argv[0]**.) Strings pointed to by **argv[1]** through **argv[argc - 1]** represent program parameters.

The parameters **argc** and **argv** are modifiable and retain their last-stored values between program startup and program termination.

ANSI 2.2.1 Members of source and execution character sets

The source character set is the set of legal characters that can appear in source files. For Microsoft C, the source character set is the standard ASCII character set.

ANSI 2.2.1.2 Shift states for multibyte characters

ANSI 3.1.3.4 The value of an integer character constant that contains more than one character or a wide character constant that contains more than one multibyte character

The regular character constant, 'ab' has the integer value (int)0x6162. When there is more than one byte, previously read bytes are shifted left by the value of **CHAR_BIT** and the next byte is compared using the bitwise-OR operator with the low **CHAR_BIT** bits. The number of bytes in the multibyte character constant cannot exceed sizeof(int), which is 4 for 32-bit target code.

The multibyte character constant is read as above and this is converted to a wide-character constant using the mbtowc run-time function. If the result is not a valid wide-character constant, an error is issued. In any event, the number of bytes examined by the mbtowc function is limited to the value of MB_CUR_MAX.

|----------------|---------------------------|
| unsigned short | 0 to 65535 |
| signed short | -32768 to 32767 |
| unsigned long | 0 to 4294967295 |

ANSI 3.2.1.2 The result of converting an integer to a shorter signed integer, or the result of converting an unsigned integer to a signed integer of equal length, if the value cannot be represented

When a **long** integer is cast to **a short**, or a **short** is cast to a char, the least-significant bytes are retained.

For example, this line

```
short x = (short)0x12345678L;
```

assigns the value 0x5678 to x, and this line

char y = (char)0x1234;

assigns the value 0x34 to y.

When signed variables are converted to unsigned and vice versa, the bit patterns remain the same. For example, casting -2 (0xFE) to an unsigned value yields 254 (also 0xFE).

Right Shifts

10/11/2017 • 1 min to read • Edit Online

The result of a right shift of a negative-value signed integral type

Shifting a negative value to the right yields half the absolute value, rounded down. For example, a signed value of -253 (hex 0xFF03, binary 11111111 00000011) shifted right one bit produces -127 (hex 0xFF81, binary 11111111 10000001). A positive 253 shifted right produces +126.

Right shifts preserve the sign bit of signed integral types. When a signed integer shifts right, the most-significant bit remains set. For example, if 0xF0000000 is a signed int, a right shift produces 0xF8000000. Shifting a negative int right 32 times produces 0xFFFFFFFF.

When an unsigned integer shifts right, the most-significant bit is cleared. For example, if 0xF000 is unsigned, the result is 0x7800. Shifting an unsigned or positive int right 32 times produces 0x00000000.

ANSI 3.2.1.3 The direction of truncation when an integral number is converted to a floating-point number that cannot exactly represent the original value

When an integral number is cast to a floating-point value that cannot exactly represent the value, the value is rounded (up or down) to the nearest suitable value.

For example, casting an **unsigned long** (with 32 bits of precision) to a **float** (whose mantissa has 23 bits of precision) rounds the number to the nearest multiple of 256. The **long** values 4,294,966,913 to 4,294,967,167 are all rounded to the **float** value 4,294,967,040.

ANSI 3.3.2.3 A member of a union object is accessed using a member of a different type

If a union of two types is declared and one value is stored, but the union is accessed with the other type, the results are unreliable.

For example, a union of **float** and <u>int</u> is declared. A **float** value is stored, but the program later accesses the value as an <u>int</u>. In such a situation, the value would depend on the internal storage of **float** values. The integer value would not be reliable.

ANSI 3.5.2.1 The padding and alignment of members of structures and whether a bit field can straddle a storage-unit boundary

Structure members are stored sequentially in the order in which they are declared: the first member has the lowest memory address and the last member the highest.

Every data object has an alignment-requirement. The alignment-requirement for all data except structures, unions, and arrays is either the size of the object or the current packing size (specified with either /Zp or the pack pragma, whichever is less). For structures, unions, and arrays, the alignment-requirement is the largest alignment-requirement of its members. Every object is allocated an offset so that

offset % alignment-requirement == 0

Adjacent bit fields are packed into the same 1-, 2-, or 4-byte allocation unit if the integral types are the same size and if the next bit field fits into the current allocation unit without crossing the boundary imposed by the common alignment requirements of the bit fields.

ANSI 3.5.2.1 The order of allocation of bit fields within an int

    unsigned b : 5;
    unsigned c : 7;
} test;

int main( void )
{
    test.a = 2;

    test.c = 0;
}
```

the bits would be arranged as follows:

```
00000001 11110010
ccccccb bbbbaaaa
```

Since the 80x86 processors store the low byte of integer values before the high byte, the integer 0x01F2 above would be stored in physical memory as 0xF2 followed by 0x01.

ANSI 3.8.2 The method for locating includable source files

For file specifications enclosed in angle brackets, the preprocessor does not search directories of the parent files. A "parent" file is the file that has the #include directive in it. Instead, it begins by searching for the file in the directories specified on the compiler command line following /I. If the /I option is not present or fails, the preprocessor uses the INCLUDE environment variable to find any include files within angle brackets. The INCLUDE environment variable can contain multiple paths separated by semicolons (;). If more than one directory appears as part of the /I option or within the INCLUDE environment variable, the preprocessor searches them in the order in which they appear.

ANSI 3.8.2 The support for quoted names for includable source files

If you specify a complete, unambiguous path specification for the include file between two sets of double quotation marks (" "), the preprocessor searches only that path specification and ignores the standard directories.

For include files specified as #include "path-spec", directory searching begins with the directories of the parent file, then proceeds through the directories of any grandparent files. Thus, searching begins relative to the directory containing the source file currently being processed. If there is no grandparent file and the file has not been found, the search continues as if the filename were enclosed in angle brackets.

ANSI 3.8.2 The mapping of source file character sequences

Preprocessor statements use the same character set as source file statements with the exception that escape sequences are not supported.

Thus, to specify a path for an include file, use only one backslash:

```
#include "path1\path2\myfile"
```

Within source code, two backslashes are necessary:

```
fil = fopen( "path1\\path2\\myfile", "rt" );
```

10/11/2017 • 1 min to read • Edit Online

ANSI 4.10.4.4 The set of environment names and the method for altering the environment list used by the getenv function

The set of environment names is unlimited.

To change environment variables from within a C program, call the _putenv function. To change environment variables from the command line in Windows, use the SET command (for example, SET LIB = D:\ LIBS).

Environment variables set from within a C program exist only as long as their host copy of the operating system command shell is running (CMD.EXE or COMMAND.COM). For example, the line

```
system( SET LIB = D:\LIBS );
```

would run a copy of the command shell (CMD.EXE), set the environment variable LIB, and return to the C program, exiting the secondary copy of CMD.EXE. Exiting that copy of CMD.EXE removes the temporary environment variable LIB.

Likewise, changes made by the _putenv function last only until the program ends.
